# PREFACE

---

Invention is often born of the need, or just the desire, to improve something. This simple statement (a restatement, in a way, of the old saw “necessity is the mother of invention”) is the driving force behind the development of the *Handbook of Materials Selection*. The audience for this handbook consists of practicing engineers and the people who work with them, all of whom need to determine what materials they might specify, order, and use to make something better, whether it’s a dental implant, an electronic package, an airplane, or a highway overpass. The choices are not always as clear cut, nor are they as straightforward, as they once were. In the past, one material (e.g., steel) or a class of materials (e.g., metals) might have been all an engineer would have needed to consider for a particular application. But now different classes of materials compete for consideration, in order that a manufactured part or assembly be as inexpensive, or as light, or as long-lasting as possible, to name just a few factors that might have to be taken into account. So whereas an engineer might have turned in the past to a single supplier’s materials properties tables to make a selection, now he or she might first turn to the engineer’s most trusted information source—colleagues, whose collective expertise can be brought to bear on an improved materials selection procedure.

So an important purpose of a publication such as this handbook is to assemble a collection of experts to provide advice to an engineer. If a handbook is to do this job effectively, its assigned experts should have a wide range of professional experience. They should have worked in a variety of settings. In keeping with this concept, the *Handbook of Materials Selection* is the product of the efforts of over 50 contributors who have experience in five different environments: a little over 40 percent are from mainly industrial backgrounds; a little under 30 percent are U.S. university faculty members, many with some experience in industry, while another 10 percent are, or have been until recently, on the faculty of academic institutions in Egypt, Israel, Germany, and England; the rest work at U.S. government installations or at research institutes, both private and university affiliated.

Whatever their background and experience may be, the contributors to this handbook have written in a style that reflects practical discussion informed by real-world experience. The intent is for readers to feel that they are in the presence of experienced engineers, materials specialists, teachers, researchers, and consultants who are well acquainted with the multiplicity of issues that govern the selection of materials for industrial applications. At the same time, the level is such that students and recent graduates can find the handbook as accessible as experienced engineers.

As much as practicable, contributors have employed visual displays, such as tables, charts, and photographs, to illustrate the points they make and the ex-

amples they draw on. They have discussed current trends in the specification, availability, and use of materials. Also, wherever appropriate, discussion enables readers to look into the near-term future.

Nevertheless, no information resource, I mean no handbook, no shelf of books, not even a web site or a portal on the Internet (not yet, at least), can hope to inspire every new product whose successful introduction and long service life are predicated on innovative and adroit materials selection, much less inspire every new version of existing products that is cheaper, lighter, or flashier than its predecessors because of a clever material substitution. Why, then, develop a one-volume *Handbook of Materials Selection*? The powerful premise driving this 1,500-page handbook is that, in terms of materials selection, what works now, as well as what has failed in the past, can serve as an experiential platform on which practicing engineers can employ the modern multidisciplinary training they now receive.

My intention has been to create a practical reference for engineers wanting to explore questions about selecting materials for specific industrial applications. In my view, there are two sets of useful questions worth exploring. One set covers practical examples of the what, why, and how of materials selection:

What materials have been used in particular industrial applications?

Why were these materials selected?

Were the materials processed in special ways?

How did material properties relate to performance in service?

Were there any problems initially, and did any develop later?

What precautions are recommended?

What were the key tradeoffs between properties and performance?

What were the limitations imposed by the selected materials?

A second set of questions relates to a practicing engineer's particular design situation:

What materials might have the characteristics that meet the needs of the application I'm working on?

Where would I find information about such materials?

What processing techniques might I use to create parts or components from these materials?

How do I take into account properties and manufacturing processes in the design process?

How would I confirm that the materials I specify and purchase have the properties I'm looking for?

How does the organization I'm working for go about supplying the materials required by the design I'm proposing, and what limitations may be imposed on my selection by such factors as cost, environmental degradation, etc.?

The emphasis in the handbook is on practical issues rather than on basic science, on design and manufacturability issues, on where to find properties information, much of which is now electronic, and on instructive applications and case studies where engineers have taken advantage of distinctive properties offered by different classes of materials. Metals, nonmetallic materials, including plastics and ceramics, and composites get equal coverage, as appropriate.

In order to answer such questions as the ones I have posed above, I arranged the contents of the handbook in seven parts. The first part, just one chapter long, but important nonetheless and a good introduction to the field of materials selection, is on quantitative methods that a practitioner can apply to materials selection problems. The second part covers the range of major materials—metallic, nonmetallic, and composite, from the tried and true to the new and novel—that engineers use nowadays to make things. A couple of these chapters deal specifically with the potential problems that practitioners should be aware of when selecting particular materials.

The third part of the handbook covers sources of materials data, including a librarian's advice on finding, as well as evaluating the reliability of, such data, methods for managing the data that an organization has acquired, and how the data are used for procuring materials. Once you've obtained a material, what exactly do you have? The fourth part of the handbook deals with the issue of testing—what equipment is used to determine the properties of the different classes of materials, what standards govern test procedures, and what organizations are in the business of providing testing services.

What about the life expectancy of the thing you've designed and made from the material you selected? Another important factor in materials selection is knowing how different classes of materials fail, which is the subject of the chapters that comprise the fifth part of the handbook. The final aspect of materials selection involves knowing about the manufacturing processes used to make things from available classes of materials, which is the subject of the chapters that make up the sixth part of the handbook.

The handbook's last, and largest, section, which sets it apart from other handbooks in the materials field, includes 11 chapters that deal not only with a broad range of industrial applications, but also with design and assembly issues involved in using composites and plastics, as well as chapters on materials that provide improved wear resistance. The applications chapters cover aerospace, medical, electronic, telecommunications, sports, and construction industries.

A few chapters in this handbook, which are not more than a few years old, have been repurposed from the second edition of another Wiley publication that I have developed, the *Mechanical Engineers' Handbook*. For the most part, however, the contributions in the *Handbook of Materials Selection* were cooked to order, so to speak. All of them are miracles, and I am eternally grateful to the busy men and women who took the time and trouble to write them.

My thanks to Wiley's internal and external production personnel for their speed and diligence. They, too, are in the business of making something better. Special thanks to my acquiring editor, Bob Argentieri, who shepherded the project through the corporate labyrinth. Not long after I drove down to Manhattan with the handbook manuscript in file folders in two cartons on the back seat of

my car, Bob and his wife, Anne, had their third child. She will grow up in a world changed and improved by the materials-selection decisions that engineers make every day. I hope this handbook helps to make some of those decisions the best that they can be.

### 1 INTRODUCTION

It is estimated that there are more than 40,000 currently useful metallic alloys and probably close to that number of nonmetallic engineering materials such as plastics, ceramics and glasses, composite materials, and semiconductors. This large number of materials and the many manufacturing processes available to the engineer, coupled with the complex relationships between the different selection parameters, often make the selection of a materials for a given component a difficult task. If the selection process is carried out haphazardly, there will be the risk of overlooking a possible attractive alternative material. This risk can be reduced by adopting a systematic material selection procedure. A variety of quantitative selection procedures have been developed to analyze the large amount of data involved in the selection process so that a systematic evaluation

can be made.<sup>1–11</sup> Several of the quantitative procedures can be adapted to use computers in selection from a data bank of materials.<sup>12–15</sup>

Experience has shown that it is desirable to adopt the holistic decision-making approach of concurrent engineering in product development in most industries. With concurrent engineering, materials and manufacturing processes are considered in the early stages of design and are more precisely defined as the design progresses from the concept to the embodiment and finally the detail stages. Figure 1 defines the different stages of design and shows the related activities of the material and manufacturing process selection. The figure illustrates the progressive nature of materials and process selection and defines three stages of selection—namely initial screening, developing and comparing alternatives, and selecting the optimum solution. Sections 2, 3, and 4 of this chapter discuss these three stages of material and process selection in more detail, and Section 5 gives a case study to illustrate the procedure.

Although the materials and process selection is often thought of in terms of new product development, there are many other incidents where materials substitution is considered for an existing product. Issues related to material substitution are discussed in Section 6 of this chapter.

Unlike the exact sciences, where there is normally only one single correct solution to a problem, materials selection and substitution decisions require the consideration of conflicting advantages and limitations, necessitating compromises and trade-offs; as a consequence, different satisfactory solutions are possible. This is illustrated by the fact that similar components performing similar functions, but produced by different manufacturers, are often made from different materials and even by different manufacturing processes.

## **2 INITIAL SCREENING OF MATERIALS**

In the first stages of development of a new product, the following questions may be posed: What is it? What does it do? How does it do it? To answer these questions it is necessary to specify the performance requirements of the different parts involved in the design and to broadly outline the main materials performance and processing requirements. This allows the initial screening of materials whereby certain classes of materials and manufacturing processes may be eliminated and others chosen as likely candidates.

### **2.1 Analysis of Material Performance Requirements**

The material performance requirements can be divided into five broad categories, namely functional requirements, processability requirements, cost, reliability, and resistance to service conditions.<sup>1</sup>

#### **Functional Requirements**

Functional requirements are directly related to the required characteristics of the part or the product. For example, if the part carries a uniaxial tensile load, the yield strength of a candidate material can be directly related to the load-carrying capacity of the product. However, some characteristics of the part or product may not have simple correspondence with measurable material properties, as in the case of thermal shock resistance, wear resistance, reliability, etc. Under these conditions, the evaluation process can be quite complex and may depend upon

**Fig. 1** Stages of design and the related stages of materials selection.

predictions based on simulated service tests or upon the most closely related mechanical, physical, or chemical properties. For example, thermal shock resistance can be related to thermal expansion coefficient, thermal conductivity, modulus of elasticity, ductility, and tensile strength. On the other hand, resistance to stress corrosion cracking can be related to tensile strength,  $K_{ISCC}$ , and electrochemical potential.

### **Processability Requirements**

The processability of a material is a measure of its ability to be worked and shaped into a finished part. With reference to a specific manufacturing method, processability can be defined as castability, weldability, machinability, etc. Ductility and hardenability can be relevant to processability if the material is to be deformed or hardened by heat treatment, respectively. The closeness of the stock form to the required product form can be taken as a measure of processability in some cases.

It is important to remember that processing operations will almost always affect the material properties so that processability considerations are closely related to functional requirements.

### **Cost**

Cost is usually an important factor in evaluating materials because in many applications there is a cost limit for a material intended to meet the application requirements. When the cost limit is exceeded, the design may have to be changed to allow for the use of a less expensive material. The cost of processing often exceeds the cost of the stock material. In some cases, a relatively more expensive material may eventually yield a less expensive product than a low-priced material that is more expensive to process.

### **Reliability Requirements**

Reliability of a material can be defined as the probability that it will perform the intended function for the expected life without failure. Material reliability is difficult to measure because it is not only dependent upon the material's inherent properties, but it is also greatly affected by its production and processing history. Generally, new and nonstandard materials will tend to have lower reliability than established, standard materials.

Despite difficulties of evaluating reliability, it is often an important selection factor that must be taken into account. Failure analysis techniques are usually used to predict the different ways in which a product can fail and can be considered as a systematic approach to reliability evaluation. The causes of failure of a part in service can usually be traced back to defects in materials and processing, to faulty design, unexpected service conditions, or misuse of the product.

### **Resistance to Service Conditions**

The environment in which the product or part will operate plays an important role in determining the material performance requirements. Corrosive environments, as well as high or low temperatures, can adversely affect the performance of most materials in service. Whenever more than one material is involved in an application, compatibility becomes a selection consideration. In a thermal

environment, for example, the coefficients of thermal expansion of all the materials involved may have to be similar in order to avoid thermal stresses. In wet environments, materials that will be in electrical contact should be chosen carefully to avoid galvanic corrosion. In applications where relative movement exists between different parts, wear resistance of the materials involved should be considered. The design should provide access for lubrication, otherwise self-lubricating materials have to be used.

## 2.2 Quantitative Methods for Initial Screening

Having specified the performance requirements of the different parts, the required material properties can be established for each of them. These properties may be quantitative or qualitative, essential or desirable. For example, the function of a connecting rod in an internal combustion engine is to connect the piston to the crank shaft. The performance requirements are that it should transmit the power efficiently without failing during the expected life of the engine. The essential material properties are tensile and fatigue strengths, while the desirable properties that should be maximized are processability, weight, reliability, and resistance to service conditions. All these properties should be achieved at a reasonable cost. The selection process involves the search for the material or materials that would best meet those requirements. The starting point for materials selection is the entire range of engineering materials. At this stage, creativity is essential in order to open up channels in different directions and not to let traditional thinking interfere with the exploration of ideas. A steel may be the best material for one design concept while a plastic is best for a different concept, even though the two designs provide the same function.

After all the alternatives have been suggested, the ideas that are obviously unsuitable are eliminated and attention is concentrated on those that look practical. At the end of this phase, quantitative methods can be used for initial screening in order to narrow down the choices to a manageable number for subsequent detailed evaluation. Following are some of the quantitative methods for initial screening of materials.

### Limits on Material Properties

Initial screening of materials can be achieved by first classifying their performance requirements into two main categories<sup>1</sup>:

- Rigid, or go-no-go, requirements
- Soft, or relative, requirements

Rigid requirements must be met by the material if it is to be considered at all. Such requirements can be used for the initial screening of materials to eliminate the unsuitable groups. For example, metallic materials are eliminated when selecting materials for an electrical insulator. If the insulator is to be flexible, the field is narrowed further as all ceramic materials are eliminated. Other examples of the material rigid requirements include behavior under operating temperature, resistance to corrosive environment, ductility, electrical and thermal conductivity or insulation, and transparency to light or other waves. Examples of process rigid requirements include batch size, production rate, product size and shape,

tolerances, and surface finish. Whether or not the equipment or experience for a given manufacturing process exist in a plant can also be considered as a hard requirement in many cases. Compatibility between the manufacturing process and the material is also an important screening parameter. For example, cast irons are not compatible with sheet metal forming processes and steels are not easy to process by die casting. In some cases, eliminating a group of materials results in automatic elimination of some manufacturing processes. For example, if plastics are eliminated because service temperature is too high, injection and transfer molding should be eliminated as they are unsuitable for other materials.

Soft, or relative, requirements are subject to compromise and trade-offs. Examples of soft requirements include mechanical properties, specific gravity, and cost. Soft requirements can be compared in terms of their relative importance, which depends on the application under study.

### Cost per Unit Property Method

The cost per unit property method is suitable for initial screening in applications where one property stands out as the most critical service requirement.<sup>1</sup> As an example, consider the case of a bar of a given length ( $L$ ) to support a tensile force ( $F$ ). The cross-sectional area ( $A$ ) of the bar is given by

$$A = F/S \quad (1)$$

where  $S$  = working stress of the material, which is related to its yield strength by an appropriate factor of safety.

The cost of the bar ( $C'$ ) is given by

$$C' = C\rho AL = (C\rho FL)/S \quad (2)$$

where  $C$  = cost of the material per unit mass

$\rho$  = density of the material

Since  $F$  and  $L$  are constant for all materials, comparison can be based on the cost of unit strength, which is the quantity:

$$[(C\rho)/S] \quad (3)$$

Materials with lower cost per unit strength are preferable. If an upper limit is set for the quantity  $[(C\rho)/S]$ , then materials satisfying this condition can be identified and used as possible candidates for more detailed analysis in the next stage of selection.

The working stress of the material in Eqs. 1, 2, and 3 is related to the static yield strength of the material since the applied load is static. If the applied load is alternating, it is more appropriate to use the fatigue strength of the material. Similarly, the creep strength should be used under loading conditions that cause creep.

Equations similar to 2 and 3 can be used to compare materials on the basis of cost per unit stiffness when the important design criterion is deflection in the bar. In such cases,  $S$  is replaced by the elastic modulus of the material. The

**Table 1 Formulas for Estimating Cost per Unit Property<sup>1</sup>**

| Cross Section and Loading Condition      | Cost per Unit Strength | Cost per Unit Stiffness |
|------------------------------------------|------------------------|-------------------------|
| Solid cylinder in tension or compression | $C\rho/S$              | $C\rho/E$               |
| Solid cylinder in bending                | $C\rho/S^{2/3}$        | $C\rho/E^{1/2}$         |
| Solid cylinder in torsion                | $C\rho/S^{2/3}$        | $C\rho/G^{1/2}$         |
| Solid cylindrical bar as slender column  | —                      | $C\rho/E^{1/2}$         |
| Solid rectangle in bending               | $C\rho/S^{1/2}$        | $C\rho/E^{1/3}$         |
| Thin-walled cylindrical pressure vessel  | $C\rho/S$              | —                       |

above equations can also be modified to allow comparison of different materials under loading systems other than uniaxial tension. Table 1 gives some formulas for the cost per unit property under different loading conditions based on either yield strength or stiffness.

### Ashby's Method

Ashby's material selection charts<sup>4,5,9,10</sup> are also useful for initial screening of materials. Figure 2 plots the strength against density for a variety of materials. Depending upon the geometry and type of loading, different  $S$ - $\rho$  relationships apply as shown in Table 1. For simple axial loading, the relationship is  $S/\rho$ . For solid rectangle under bending,  $S^{1/2}/\rho$  applies, and for solid cylinder under bending or torsion the relationship  $S^{2/3}/\rho$  applies. Lines with these slopes are shown in Fig. 2. Thus if a line is drawn parallel to the line  $S/\rho = C$ , all the materials that lie on the line will perform equally well under simple axial loading conditions. Materials above the line are better and those below it are worse. A similar diagram can be drawn for elastic modulus against density and formulas similar to those in Table 1 can be used to screen materials under conditions where stiffness is a major requirement

### Dargie's Method

The initial screening of materials and processes can be a tedious task if performed manually from handbooks and supplier catalogs. This difficulty has prompted the introduction of several computer-based systems for materials and/or process selection.<sup>12-15</sup> As an illustrative example, the system (MAPS 1) proposed by Dargie et al.<sup>15</sup> will be briefly described here. For this system, Dargie et al. proposed a part classification code similar to that used in group technology.

The first five digits of the MAPS 1 code are related to the elimination of unsuitable manufacturing processes. The first digit is related to the batch size. The second digit characterizes the bulk and depends on the major dimension and whether the part is long, flat, or compact. The third digit characterizes the shape, which is classified on the basis of being prismatic, axisymmetric, cup shaped, nonaxisymmetric, and nonprismatic. The fourth digit is related to tolerance and the fifth digit is related to surface roughness

The next three digits of the MAPS 1 code are related to the elimination of unsuitable materials. The sixth digit is related to service temperature. The seventh digit is related to the acceptable corrosion rate. The eighth digit characterizes the type of environment to which the part is exposed.

The system uses two types of databases for preliminary selection:

**Fig. 2** Example of Ashby's materials selection charts (from Ref. 10, with permission from The Institute of Materials).

- Suitability matrices
- Compatibility matrix

The suitability matrices deal with the suitability of processes and materials for the part under consideration. Each of the code digits has a matrix. The columns of the matrix correspond to the value of the digit and the rows correspond to the processes and materials in the database. The elements of the matrix are either 0, indicating unsuitability, or 2 indicating suitability.

The compatibility matrix expresses the compatibility of the different combinations of processes and materials. The columns of the matrix correspond to the materials while the rows correspond to the processes. The elements of the matrix are either 0 for incompatible combinations, 1 for difficult or unusual combinations, or 2 for combinations used in usual practice.

Based on the part code, the program generates a list of candidate combinations of materials and processes to produce it. This list helps the designer to identify

possible alternatives early in the design process and to design for ease of manufacture.

3 COMPARING ALTERNATIVE SOLUTIONS

After narrowing down the field of possible materials using one or more of the quantitative initial screening methods described in Section 2, quantitative methods can be used to further narrow the field of possible materials and matching manufacturing processes to a few optimum candidates that have good combinations of soft requirements. Several such methods are described in Refs. 1 and 2 and following is a description of one of the methods.

3.1 Weighted-Properties Method

In the weighted-properties method each material requirement, or property, is assigned a certain weight, depending on its importance to the performance of the part in service.<sup>1</sup> A weighted-property value is obtained by multiplying the numerical value of the property by the weighting factor ( $\alpha$ ). The individual weighted-property values of each material are then summed to give a comparative materials performance index ( $\gamma$ ). Materials with the higher performance index ( $\gamma$ ) are considered more suitable for the application.

Digital Logic Method

In the cases where numerous material properties are specified and the relative importance of each property is not clear, determinations of the weighting factors,  $\alpha$ , can be largely intuitive, which reduces the reliability of selection. The digital logic approach can be used as a systematic tool to determine  $\alpha$ .<sup>1</sup> In this procedure evaluations are arranged such that only two properties are considered at a time. Every possible combination of properties or goals is compared and no shades of choice are required, only a yes or no decision for each evaluation. To determine the relative importance of each property or goal a table is constructed, the properties or goals are listed in the left-hand column, and comparisons are made in the columns to the right, as shown in Table 2.

In comparing two properties or goals, the more important goal is given numerical one (1) and the less important is given zero (0). The total number of possible decisions  $N = n(n - 1)/2$ , where  $n$  is the number of properties or goals under consideration. A relative emphasis coefficient or weighting factor,

Table 2 Determination of Relative Importance of Goals Using Digital Logic Method<sup>1</sup>

| Goals                              | Number of Positive Decisions $N = n(n - 1)/2$ |   |   |   |   |   |   |   |   |    | Positive Decisions | Relative Emphasis Coefficient $\alpha$ |
|------------------------------------|-----------------------------------------------|---|---|---|---|---|---|---|---|----|--------------------|----------------------------------------|
|                                    | 1                                             | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |                    |                                        |
| 1                                  | 1                                             | 1 | 0 | 1 |   |   |   |   |   |    | 3                  | 0.3                                    |
| 2                                  | 0                                             |   |   |   | 1 | 0 | 1 |   |   |    | 2                  | 0.2                                    |
| 3                                  |                                               | 0 |   |   | 0 |   |   | 1 | 0 |    | 1                  | 0.1                                    |
| 4                                  |                                               |   | 1 |   |   | 1 |   | 0 |   | 0  | 2                  | 0.2                                    |
| 5                                  |                                               |   |   | 0 |   |   | 0 |   | 1 | 1  | 2                  | 0.2                                    |
| Total number of positive decisions |                                               |   |   |   |   |   |   |   |   |    | 10                 | $\Sigma\alpha = 1.0$                   |

$\alpha$ , for each goal is obtained by dividing the number of positive decisions for each goal ( $m$ ) into the total number of possible decisions ( $N$ ). In this case  $\sum \alpha = 1$ .

To increase the accuracy of decisions based on the digital logic approach, the yes–no evaluations can be modified by allocating gradation marks ranging from 0 (no difference in importance) to 3 (large difference in importance). In this case, the total gradation marks for each selection criterion are reached by adding up the individual gradation marks. The weighting factors are then found by dividing these total gradation marks by their grand total.

### Performance Index

In its simple form, the weighted-properties method has the drawback of having to combine unlike units, which could yield irrational results. This is particularly true when different mechanical, physical, and chemical properties with widely different numerical values are combined. The property with higher numerical value will have more influence than is warranted by its weighting factor. This drawback is overcome by introducing scaling factors. Each property is so scaled that its highest numerical value does not exceed 100. When evaluating a list of candidate materials, one property is considered at a time. The best value in the list is rated as 100 and the others are scaled proportionally. Introducing a scaling factor facilitates the conversion of normal material property values to scaled dimensionless values. For a given property, the scaled value,  $B$ , for a given candidate material is equal to:

$$B = \text{Scaled property} = \frac{\text{Numerical value of property} \times 100}{\text{Maximum value in the list}} \quad (4)$$

For properties such as cost, corrosion or wear loss, weight gain in oxidation, etc., a lower value is more desirable. In such cases, the lowest value is rated as 100 and  $B$  is calculated as:

$$B = \text{Scaled property} = \frac{\text{Minimum value in the list} \times 100}{\text{Numerical value of property}} \quad (5)$$

For material properties that can be represented by numerical values, application of the above procedure is simple. However, with properties such as corrosion and wear resistance, machinability and weldability, etc., numerical values are rarely given and materials are usually rated as very good, good, fair, poor, etc. In such cases, the rating can be converted to numerical values using an arbitrary scale. For example, corrosion resistance rating—excellent, very good, good, fair, and poor—can be given numerical values of 5, 4, 3, 2, and 1, respectively. After scaling the different properties, the material performance index ( $\gamma$ ) can be calculated as:

$$\text{Material performance index} = \gamma = \sum_{i=1}^n B_i \alpha_i \quad (6)$$

where  $i$  is summed over all the  $n$  relevant properties.

Cost (stock material, processing, finishing, etc.) can be considered as one of the properties and given the appropriate weighting factor. However, if there is a large number of properties to consider, the importance of cost may be emphasized by considering it separately as a modifier to the material performance index ( $\gamma$ ). In the cases where the material is used for space filling, cost can be introduced on per unit volume basis. A figure of merit ( $M$ ) for the material can then be defined as:

$$M = \gamma/(C\rho) \quad (7)$$

where  $C$  = total cost of the material per unit weight (stock, processing, finishing, etc.)  
 $\rho$  = density of the material.

When an important function of the material is to bear stresses, it may be more appropriate to use the cost of unit strength instead of the cost per unit volume. This is because higher strength will allow less material to be used to bear the load, and the cost of unit strength may be a better representative of the amount of material actually used in making the part. In this case, Eq. 7 is rewritten as:

$$M = \gamma/C' \quad (8)$$

where  $C'$  is determined from Table 1 depending on the type of loading.

This argument may also hold in other cases where the material performs an important function such as electrical conductivity or thermal insulation. In these cases the amount of the material, and consequently the cost, are directly affected by the value of the property.

When a large number of materials with a large number of specified properties are being evaluated for selection, the weighted-properties method can involve a large number of tedious and time-consuming calculations. In such cases, the use of a computer would facilitate the selection process. The steps involved in the weighted-properties method can be written in the form of a simple computer program to select materials from a data bank. An interactive program can also include the digital logic method to help in determining the weighting factors.

#### 4 SELECTING THE OPTIMUM SOLUTION

Candidates that have the most promising performance indices can each now be used to develop a detail design. Each detail design will exploit the points of strength of the material, avoid the weak points, and reflect the requirements of the manufacturing processes needed for the material. The different designs are then compared, taking the cost elements into consideration, in order to arrive at the optimum design–material–process combination.<sup>16</sup>

#### 5 CASE STUDY IN MATERIAL SELECTION

The following case study illustrates the procedure for materials selection as described in Sections 2, 3, and 4 and is based on Ref. 16. The objective is to select the least expensive component that satisfies the requirements for a simple structural component for a sailing-boat mast in the form of a hollow cylinder of

length 1000 mm, which is subjected to compressive axial forces of 153 kN. Because of space and weight limitations, the outer diameter of the component should not exceed 100 mm, the inner diameter should not be less than 84 mm, and the mass should not exceed 3 kg. The component will be subjected to mechanical impact and spray of water. Assembly to other components requires the presence of relatively small holes.

### 5.1 Material Performance Requirements

Possible modes of failure and the corresponding material properties that are needed to resist failure for the present component include:

- Catastrophic fracture due to impact loading, especially near assembly holes, is resisted by high fracture toughness of the material. This is a rigid material requirement and will be used for initial screening of materials.
- Plastic yielding is resisted by high yield strength. This is a soft material requirement, but a lower limit will be determined by the limitation on the outer diameter.
- Local and global buckling are resisted by high elastic modulus. This is a soft material requirement, but a lower limit will be determined by the limitation on the outer diameter.
- Internal fiber buckling for fiber-reinforced materials is resisted by high modulus of elasticity of the matrix and high volume fraction of fibers in the loading direction. This is a soft material requirement, but a lower limit will be determined by the limitation on the outer diameter.
- Corrosion, which can be resisted either by selecting materials with inherently good corrosion resistance or by protective coating.
- Reliability of the component in service. A factor of safety of 1.5 is taken for the axial loading, i.e., the working axial force will be taken as 230 kN in order to improve reliability.

In addition to the above requirements the limitations set on dimensions and weight should be observed.

### 5.2 Initial Screening of Materials

The requirement for fracture toughness of the material is used to eliminate ceramic materials. Because of the limitations set on the outer and inner diameters, the maximum possible cross section of the component is about 2300 mm<sup>2</sup>. To avoid yielding under the axial working load, the yield strength of the material should be more than 100 MPa, which excludes engineering polymers, woods, and some of the lower strength engineering alloys; see Fig. 2. Corrosion resistance is desirable but will not be considered a factor for screening since the possibility of protection for less corrosion materials exists but will be considered as a soft requirement.

### 5.3 Comparing Alternative Solutions

Table 3 shows a sample of materials that satisfy the conditions set in the initial screening stage. In a real-life situation the list in the table could be much longer,

**Table 3 Properties of Sample Candidate Materials<sup>16</sup>**

| Material                              | Yield Strength (MPa) | Elastic Modulus (GPa) | Specific Gravity | Corrosion Resistance <sup>a</sup> | Cost Category <sup>b</sup> |
|---------------------------------------|----------------------|-----------------------|------------------|-----------------------------------|----------------------------|
| AISI 1020<br>(UNS G10200)             | 280                  | 210                   | 7.8              | 1                                 | 5                          |
| AISI 1040<br>(UNS G10400)             | 400                  | 210                   | 7.8              | 1                                 | 5                          |
| ASTM A242 type 1<br>(UNS K11510)      | 330                  | 212                   | 7.8              | 1                                 | 5                          |
| AISI 4130<br>(UNS G41300)             | 1520                 | 212                   | 7.8              | 4                                 | 3                          |
| AISI 316<br>(UNS S31600)              | 205                  | 200                   | 7.98             | 4                                 | 3                          |

<sup>a</sup> 5 Excellent, 4 Very good, 3 Good, 2 Fair, 1 Poor.

<sup>b</sup> 5 Very inexpensive, 4 Inexpensive, 3 Moderate price, 2 Expensive, 1 Very expensive.

but the intent here is to illustrate the procedure. The yield strength, elastic modulus, specific gravity, corrosion resistance, and cost category are given for each of the materials. At this stage, it is sufficient to classify materials into very inexpensive, inexpensive, etc. Better estimates of the material and manufacturing cost will be needed in making the final decision in selection. Because the weight of the component is important in this application, specific strength and specific modulus would be better indicators of the suitability of the material (Table 4). The relative importance of the material properties is given in Table 5, and the performance indices of the different materials, as determined by the weighted-properties method, are given in Table 6. The seven candidate materials with high-performance indices ( $\gamma > 45$ ) are selected for making actual component designs.

#### 5.4 Selecting the Optimum Solution

As shown earlier, the possible modes of failure of a hollow cylinder include yielding, local and global buckling, and internal fiber buckling. These four failure modes are used to develop the design formulas for the mast component. For

Table 4 Properties of Sample Candidate Materials<sup>16</sup>

| Material                              | Specific Strength (MPa) | Specific Modulus (GPa) | Corrosion Resistance <sup>a</sup> | Cost Category <sup>b</sup> |

more details on the design and optimization procedure or Eqs. 9–12, please refer to Ref. 16.

Condition for yielding:  $F/A < \sigma_y$  (9)

where  $\sigma_y$  = yield strength of the material  
 $F$  = external working axial force  
 $A$  = cross sectional area

Condition for local buckling:  $F/A < 0.121ES/D$  (10)

Table 5 Weighting Factors

| Property                      | Specific Strength (MPa) | Specific Modulus (GPa) | Corrosion Resistance | Relative Cost |
|-------------------------------|-------------------------|------------------------|----------------------|---------------|
| Weighting factor ( $\alpha$ ) | 0.3                     | 0.3                    | 0.15                 | 0.25          |

with the space and weight limitations, AA 2024 T6 is selected since it gives the least expensive solution.

6 MATERIALS SUBSTITUTION

The common reasons for materials substitution include:

- Taking advantage of new materials or processes
- Improving service performance, including longer life and higher reliability
- Meeting new legal requirements
- Accounting for changed operating conditions
- Reducing cost and making the product more competitive

Generally, a simple substitution of one material for another does not produce an optimum solution. This is because it is not possible to realize the full potential of a new material unless the component is redesigned to exploit its strong points and manufacturing characteristics. Following is a brief description of some of the quantitative methods that are available for making decisions in materials substitution.

6.1 Pugh Method

The Pugh method<sup>17</sup> is useful as an initial screening method in the early stages of design. In this method, a decision matrix is constructed as shown in Table 8. Each of the properties of a possible alternative new material is compared with the corresponding property of the currently used material and the result is recorded in the decision matrix as (+) if more favorable, (–) if less favorable, and (0) if the same. The decision on whether a new material is better than the currently used material is based on the analysis of the result of comparison, i.e., the total number of (+), (–), and (0). New materials with more favorable properties than drawbacks are selected as serious candidates for substitution and are used to redesign the component and for detailed analysis.

Table 8 Example of Use of Pugh Decision Matrix for Materials Substitution

| Property   | Currently Used Material | New Material (1) | New Material (2) | New Material (3) |
|------------|-------------------------|------------------|------------------|------------------|
| Property 1 | C1                      | –                | +                | +                |
| Property 2 | C2                      | +                | +                | +                |
| Property 3 | C3                      | +                | +                | –                |
| Property 4 | C4                      | 0                | +                | –                |
| Property 5 | C5                      | –                | 0                | –                |
| Property 6 | C6                      | 0                | 0                | 0                |
| Property 7 | C7                      | –                | –                | 0                |
| Property 8 | C8                      | –                | +                | 0                |
| Property 9 | C9                      | –                | 0                | 0                |
| Total (+)  |                         | 2                | 5                | 2                |
| Total (–)  |                         | 5                | 1                | 3                |
| Total (0)  |                         | 2                | 3                | 4                |

## 6.2 Cost–Benefit Analysis

The cost–benefit analysis is more suitable for the detailed analysis involved in making the final material substitution decision.<sup>1</sup> Because new materials are usually more complex and often require closer control and even new technologies for their processing, components made from such materials are more expensive. This means that for materials substitution to be economically feasible, the economic gain as a result of improved performance  $\Delta B$  should be more than the additional cost incurred as a result of substitution  $\Delta C$ .

$$\Delta B - \Delta C > 1 \quad (13)$$

For this analysis it is convenient to divide the cost of materials substitution  $\Delta C$  into:

- *Cost Differences in Direct Material and Labor.* New materials often have better performance but are more expensive. When smaller amounts of the new material are used to make the product, the increase in direct material cost may not be as great as it would appear at first. Cost of labor may not be an important factor in substitution if the new materials do not require new processing techniques and assembly procedures. If, however, new processes are needed, new cycle times may result and the difference in productivity has to be carefully assessed.
- *Cost of Redesign and Testing.* Using new materials usually involves design changes and testing of components to ensure that their performance meets the requirements. The cost of redesign and testing can be considerable in the case of critical components.
- *Cost of New Tools and Equipment.* Changing materials can have considerable effect on life and cost of tools, and it may influence the heat treatment and finishing processes. This can be a source of cost saving if the new material does not require the same complex treatment or finishing processes used for the original material. The cost of equipment needed to process new materials can be considerable if the new materials require new production facilities as in the case of replacing metals with plastics.

Based on the above analysis, the total cost ( $\Delta C$ ) of substituting a new material,  $n$ , in place of an original material,  $o$ , in a given part is:

$$\Delta C = (P_n M_n - P_o M_o) + f(C_t/N) + (T_n - T_o) + (L_n - L_o) \quad (14)$$

where  $P_n, P_o$  = price/unit mass of new and original materials used in the part  
 $M_n, M_o$  = mass of new and original materials used in the part  
 $f$  = capital recovery factor; it can be taken as 15% in the absence of information

$C_t$  = cost of transition from original to new materials

$N$  = total number of new parts produced

$T_n, T_o$  = tooling cost per part for new and original materials

$L_n, L_o$  = labor cost per part using new and old materials

The gains as a result of improved performance  $\Delta B$  can be estimated based on the expected improved performance of the component, which can be related to the increase in performance index of the new material compared with the currently used material. Such increases include the saving gained as a result of weight reduction or increased service life of the component.

$$\Delta B = A(\gamma_n - \gamma_o) \quad (15)$$

where  $\gamma_n$ ,  $\gamma_o$  = performance indices of the new and original materials, respectively

$A$  = benefit of improved performance of the component expressed in dollars per unit increase in material performance index  $\gamma$ .

## 7 CASE STUDY IN MATERIALS SUBSTITUTION

In the case study in materials selection that was discussed in Section 5, the aluminum alloy AA 2024 T6 was selected since it gives the least expensive solution. Of the seven materials in Table 7, AA 6061 T6, epoxy-70% glass fabric, and epoxy-62% aramid fabric result in components that are heavier and more expensive than those of the other four materials and will be rejected as they offer no advantage. Of the remaining four materials, AA 2024 T6 results in the least expensive but the heaviest component. The other three materials—AA 2014 T6, AA 7075 T6, and epoxy-63% carbon fabric—result in progressively lighter components at progressively higher cost.

For the cases where it is advantageous to have a lighter component, the cost-benefit analysis can be used in finding a suitable substitute for AA 2024 T6 alloy. For this purpose Eq. 15 is used with the performance index  $\gamma$  being considered as the weight of the component and  $\Delta C$  being the difference in cost of component and  $A$  is the benefit expressed in dollars, of reducing the mass by 1 kg. Comparing the materials in pairs shows that:

- |                                         |                                     |
|-----------------------------------------|-------------------------------------|
| For $A < \$7/\text{kg}$ saved,          | AA 2024 T6 is the optimum material. |
| For $A = \$7 - \$60.5/\text{kg}$ saved, | AA 7075 T6 is a better substitute.  |
| For $A > \$60.5/\text{kg}$ saved,       | Epoxy-63% carbon fabric is optimum. |

## 8 SOURCES OF INFORMATION AND COMPUTER-ASSISTED SELECTION

One essential requisite to successful materials selection is a source of reliable and consistent data on materials properties. There are many sources of information, which include governmental agencies, trade associations, engineering societies, textbooks, research institutes, and materials producers. The ASM International has recently published a directory of materials property databases<sup>18</sup> that contains more than 500 data sources, including both specific databases and data centers. For each source, the directory gives a brief description of the available information, address, telephone number, e-mail, web site, and approximate cost if applicable. The directory also has indices by material and by property to help the user in locating the most appropriate source of material information. Much of the information is available on CD-ROM or PC disk, which makes it possible to integrate the data source in computer-assisted selection systems.

Other useful reviews of the sources of materials property data and information are also given in Refs. 19 and 20.

### 8.1 Computerized Materials Databases

Computerized materials databases are an important part of any computer-aided system for selection. With an interactive database, as in the case of *ASM Metal Selector*,<sup>21</sup> the user can define and redefine the selection criteria to gradually sift the materials and isolate the candidates that meet the requirements. In many cases, sifting can be carried out according to different criteria such as:

1. Specified numeric values of a set of material properties
2. Specified level of processability such as machinability, weldability, formability, availability, processing cost, etc.
3. Class of material, e.g., fatigue resistant, corrosion resistant, heat resistant, electrical materials, etc.
4. Forms such as rod, wire, sheet, tube, cast, forged, welded, etc.
5. Designations: Unified Numbering System (UNS) numbers, American Iron and Steel Institute (AISI) numbers, common names, material group or country of origin
6. Specifications, which allows the operator to select the materials that are acceptable to organizations such as the American Society for Testing and Materials (ASTM) and the Society of Automotive Engineers (SAE)
7. Composition, which allows the operator to select the materials that have certain minimum and/or maximum values of alloying elements

More than one of the above sifting criteria can be used to identify suitable materials. Sifting can be performed in the AND or OR modes. The AND mode narrows the search since the material has to conform to all the specified criteria. The OR mode broadens the search since materials that satisfy any of the requirements are selected.

The number of materials that survive the sifting process depends on the severity of the criteria used. At the start of sifting, the number of materials shown on the screen is the total in the database. As more restrictions are placed on the materials, the number of surviving materials gets smaller and could reach 0, i.e., no materials qualify. In such cases, some of the restrictions have to be relaxed and the sifting restarted.

### 8.2 Computer Assistance in Making Final Selection

Integrating material property database with design algorithms and computer-aided design (CAD)/computer-aided manufacturing (CAM) programs has many benefits including homogenization and sharing of data in the different departments, decreased redundancy of effort, and decreased cost of information storage and retrieval. Several such systems have been cited in Ref. 18, including:

- The Computerized Application and Reference System (CARS), developed from the *AISI Automotive Steel Design Manual*, performs first-order analysis of design using different steels.

- Aluminum Design System (ADS), developed by the Aluminum Association (U.S.), performs design calculations and conformance checks of aluminum structural members with the design specifications for aluminum and its alloys.
- Material Selection and Design for fatigue life predictions, developed by ASM International, aids in the design of machinery and engineering structures using different engineering materials.
- Machine Design's Materials Selection, developed by Penton Media (U.S.), combines the properties for a wide range of materials and the data set for design analysis.

### 8.3 Expert Systems

Expert systems, also called knowledge-based systems, are computer programs that simulate the reasoning of a human expert in a given field of knowledge. Expert systems rely on heuristics, or rules of thumb, to extract information from a large knowledge base. Expert systems typically consist of three main components:

- The knowledge base contains facts and expert-level heuristic rules for solving problems in a given domain. The rules are normally introduced to the system by domain experts through a knowledge engineer.
- The inference engine provides an organized procedure for sifting through the knowledge base and choosing applicable rules in order to reach the recommend solutions. The inference engine also provides a link between the knowledge base and the user interface.
- The user interface allows the user to input the main parameters of the problem under consideration. It also provides recommendations and explanations of how such recommendations were reached.

A commonly used format for the rules in the knowledge base is in the form:

IF (condition 1) and/or (condition 2)  
THEN (conclusion 1)

For example, in the case of FRP selection:

IF: required elastic modulus, expressed in GPa, is more than 150 and specific gravity less than 1.7.  
THEN: oriented carbon fibers at 60% by volume.

Expert systems are finding many applications in industry including the areas of design, trouble-shooting, failure analysis, manufacturing, materials selection, and materials substitution.<sup>12</sup> When used to assist in materials selection, expert systems provide impartial recommendations and are able to search large databases for optimum solutions. Another important advantage of expert systems is their ability to capture valuable expertise and make it available to a wider circle of users. An example is the Chemical Corrosion Expert System, which is produced

by the National Association of Corrosion Engineers (NACE) in the United States.<sup>18</sup> The system prompts the user for information on the environmental conditions and configuration of the component and then recommends candidate materials.

### 1 INTRODUCTION

Steel is the most common and widely used metallic material in today's society. It can be cast or wrought into numerous forms and can be produced with tensile strengths exceeding 5 GPa. A prime example of the versatility of steel is in the automobile where it is the material of choice and accounts for over 60% of the weight of the vehicle. Steel is highly formable as seen in the contours of the automobile outerbody. Steel is strong and is used in the body frame, motor brackets, driveshaft, and door impact beams of the vehicle. Steel is corrosion resistant when coated with the various zinc-based coatings available today. Steel is dent resistant when compared with other materials and provides exceptional energy absorption in a vehicle collision. Steel is recycled and easily separated from other materials by a magnet. Steel is inexpensive compared with other competing materials such as aluminum and various polymeric materials.

In the past, steel has been described as an alloy of iron and carbon. Today, this description is no longer applicable since in some very important steels, e.g., interstitial-free (IF) steels and type 409 ferritic stainless steels, carbon is considered an impurity and is present in quantities of only a few parts per million. By definition, steel must be at least 50% iron and must contain one or more alloying element. These elements generally include carbon, manganese, silicon, nickel, chromium, molybdenum, vanadium, titanium, niobium, and aluminum.

Each chemical element has a specific role to play in the steelmaking process or in achieving particular properties or characteristics, e.g., strength, hardness, corrosion resistance, magnetic permeability, and machinability.

## 2 STEEL MANUFACTURE

In most of the world, steel is manufactured by integrated steel facilities that produce steel from basic raw materials, i.e., iron ore, coke, and limestone. However, the fastest growing segment of the steel industry is the “minimill” that melts steel scrap as the raw material. Both types of facilities produce a wide variety of steel forms including sheet, plate, structural, railroad rail, and bar products.

***Ironmaking.*** When making steel from iron ore, a blast furnace chemically reduces the ore (iron oxide) with carbon in the form of coke. Coke is a sponge-like carbon mass that is produced from coal by heating the coal to expel the organic matter and gasses. Limestone (calcium carbonate) is added as a flux for easier melting and slag formation. The slag, which floats atop the molten iron, absorbs many of the unwanted impurities. The blast furnace is essentially a tall hollow cylindrical structure with a steel outer shell lined on the inside with special refractory and graphite brick. The crushed or pelletized ore, coke, and limestone are added as layers through an opening at the top of the furnace, and chemical reduction takes place with the aid of a blast of preheated air entering near the bottom of furnace (an area called the bosh). The air is blown into the furnace through a number of water-cooled copper nozzles called tuyeres. The reduced liquid iron fills the bottom of the furnace and is tapped from the furnace at specified intervals of time. The product of the furnace is called pig iron because in the early days the molten iron was drawn from the furnace and cast directly into branched mold configurations on the cast house floor. The central branch of iron leading from the furnace was called the “sow” and the side branches were called “pigs.” Today the vast majority of pig iron is poured directly from the furnace into a refractory-lined vessel (submarine car) and transported in liquid form to a basic oxygen furnace (BOF) for refinement into steel.

***Steelmaking.*** In the BOF, liquid pig iron comprises the main charge. Steel scrap is added to dilute the carbon and other impurities in the pig iron. Oxygen gas is blown into the vessel by means of a top lance submerged below the liquid surface. The oxygen interacts with the molten pig iron to oxidize undesirable elements. These elements include excess carbon (because of the coke used in the blast furnace, pig iron contains over 2% carbon), manganese, and silicon from the ore and limestone and other impurities like sulfur and phosphorus. While in the BOF, the liquid metal is chemically analyzed to determine the level of carbon and impurity removal. When ready, the BOF is tilted and the liquid steel is poured into a refractory-lined ladle. While in the ladle, certain alloying elements can be added to the steel to produce the desired chemical composition. This process takes place in a ladle treatment station or ladle furnace where the steel is maintained at a particular temperature by external heat from electrodes

in the ladle placed on the ladle. After the desired chemical composition is achieved, the ladle can be placed in a vacuum chamber to remove undesirable gases such as hydrogen and oxygen. This process is called degassing and is used for higher quality steel products such as railroad rail, sheet, plate, bar, and forged products. Stainless steel grades are usually produced in an induction or electric arc furnace, sometimes under vacuum. To refine stainless steel, the argon–oxygen decarburization (AOD) process is used. In the AOD, an argon–oxygen gas mixture is injected through the molten steel to remove carbon without a substantial loss of chromium (the main element in stainless steel).

**Continuous Casting.** Today, most steel is cast into solid form in a continuous-casting (also called strand casting) machine. Here, the liquid begins solidification in a water-cooled copper mold while the steel billet, slab, or bloom is withdrawn from the bottom of the mold. The partially solidified shape is continuously withdrawn from the machine and cut to length for further processing. The continuous-casting process can proceed for days or weeks as ladle after ladle of molten steel feeds the casting machine. Some steels are not continuously cast but are poured into individual cast-iron molds to form an ingot that is later reduced in size by forging or a rolling process to some other shape. Since the continuous-casting process offers substantial economic and quality advantages over ingot casting most steel in the world is produced by continuous casting.

**Rolling/Forging.** Once cast into billet, slab, or bloom form, the steel is hot rolled through a series of rolling mills or squeezed/hammered by forging to produce the final shape. To form hot-rolled sheet, a 50- to 300-mm-thick slab is reduced to final thickness, e.g., 2 mm, in one or more roughing stands followed by a series of six or seven finishing stands. To obtain thinner steel sheet, e.g., 0.5 mm, the hot-rolled sheet must be pickled in acid to remove the iron oxide scale and further cold rolled in a series of rolling stands called a tandem mill. Because the cold-rolling process produces a hard sheet with little ductility, it is annealed either by batch annealing or continuous annealing. New casting technology is emerging where thin sheet (under 1 mm) can be directly cast from the liquid through water-cooled, rotating rolls that act as a mold as in continuous casting. This new process eliminates many of the steps in conventional hot-rolled sheet processing. Plate steels are produced by hot rolling a slab in a reversing roughing mill and a reversing finishing mill. Steel for railway rails is hot rolled from a bloom in a blooming mill, a roughing mill, and one or more finishing mills. Steel bars are produced from a heated billet that is hot rolled in a series of roughing and finishing mills. Forged steels are produced from an ingot that is heated to forging temperature and squeezed or hammered in a hydraulic press or drop forge. The processing sequence in all these deformation processes can vary depending on the design, layout, and age of the steel plant.

### 3 DEVELOPMENT OF STEEL PROPERTIES

In order to produce a steel product with the desired properties, basic metallurgical principles are used to control three things,

This means that the steel composition and processing route must be closely controlled in order to produce the proper microstructure. The final microstructure is of utmost importance in determining the properties of the steel product. This section will explore how various microstructures are developed and the unique characteristics of each microstructural component in steel. The next section will discuss how alloy composition also plays a major role.

**Iron–Carbon Equilibrium Diagram.** Since most steels contain carbon, the basic principles of microstructural development can be explained by the iron–carbon equilibrium diagram. This diagram, shown in Fig. 1, is essentially a map of the phases that exist in iron at various carbon contents and temperatures under equilibrium conditions. Iron is an interesting chemical element in that it undergoes three phase changes when heated from room temperature to liquid. For example, from room temperature to 912°C, pure iron exists as ferrite (also called alpha iron), from 912 to 1394°C, it exists as austenite (gamma iron), from 1394 to 1538°C it exists as ferrite again (delta iron), and above 1538°C it is liquid. In other words, upon heating, iron undergoes allotropic phase transformations from ferrite to austenite at 912°C, austenite to ferrite at 1394°C, and ferrite to liquid at 1538°C. Each transformation undergoes a change in crystal structure or arrangement of the iron atoms in the crystal lattice. It must be remembered that all chemical elements in their solid form have specific arrangements of atoms that are essentially the basic building blocks in producing the element in the form that we physically observe. These atomic arrangements form a lattice-work containing billions of atoms all aligned in a systematic way. Some of these lattices have a cubic arrangement, with an atom at each corner of the cube and another atom at the cube center. This arrangement is called body-centered-cubic (bcc). Others have an atom at each corner of the cube and atoms at the center of each face of the cube. This is called face-centered-cubic (fcc). Other arrangements are hexagonal, some are tetragonal, etc. As an example, pure iron as ferrite has a bcc arrangement. Austenite has a fcc arrangement. Upon heating, bcc

Fig. 1 Iron-carbon binary-phase diagram. (Source: *Steels: Heat Treatment and Processing Principles*, ASM International, Materials Park, OH 44073-0002, 1990, p. 2.)

ferrite will transform to fcc austenite at 912°C. These arrangements or crystal structures impart different properties to steel. For example, a bcc ferritic stainless steel will have properties much different from a fcc austenitic stainless steel as described later in this chapter.

Since pure iron is very soft and of low strength, it is of little interest commercially. Therefore, carbon and other alloying elements are added to enhance properties. Adding carbon to pure iron has a profound effect on ferrite and austenite discussed above. One way to understand the effect of carbon is to

examine the iron–carbon diagram (Fig. 1). This is a binary (two-element) diagram of temperature and composition (carbon content) constructed under near-equilibrium conditions. In this diagram, as carbon is added to iron, the ferrite and austenite phase fields expand and contract depending upon the carbon level and temperature. Also, there are fields consisting of two phases, e.g., ferrite plus austenite.

Since carbon has a small atomic diameter when compared with iron, it is called an interstitial element because it can fill the interstices between the iron atoms in the cubic lattice. Nitrogen is another interstitial element. On the other hand, elements such as manganese, silicon, nickel, chromium, and molybdenum have atomic diameters similar to iron and are called substitutional alloying elements. These substitutional elements can thus replace iron atoms at the cube corners, faces, or center positions. There are many binary phase diagrams (Fe–Mn, Fe–Cr, Fe–Mo, etc.) and tertiary-phase diagrams (Fe–C–Mn, Fe–C–Cr, etc.) showing the effect of interstitial and substitutional elements on the phase fields of ferrite and austenite. These diagrams are found in the handbooks listed at the end of the chapter.

Being an interstitial or a substitutional element is important in the development of steel properties. Interstitial elements such as carbon can move easily about the crystal lattice whereas a substitutional element such as manganese is much more difficult to move. The movement of elements in a crystal lattice is called diffusion. Diffusion is a controlling factor in the development of microstructure. Another factor is solubility, which is a measure of how much of a particular element can be accommodated by the crystal lattice before it is rejected. In metals when two or more elements are soluble in the crystal lattice, a solid solution is created (somewhat analogous to a liquid solution of sugar in hot coffee). For example, when added to iron, carbon has very limited solubility in ferrite but is about 100 times more soluble in austenite, as seen in the iron–carbon diagram in Fig. 2 (a limited version of the diagram in Fig. 1). The maximum solubility of carbon in ferrite is about 0.022% C at 727°C while the maximum solubility of carbon in austenite is 100 times more, 2.11% C at 1148°C. At room temperature the solubility of carbon in iron is only about 0.005%. Any amount of carbon in excess of the solubility limit is rejected from solid solution and is usually combined with iron to form an iron carbide compound called cementite. This hard and brittle compound has the chemical formula  $\text{Fe}_3\text{C}$  and a carbon content of 6.7%. This is illustrated in the following two examples. The first example is a microstructure of a very low carbon steel (0.002% C) is shown in Fig. 3a. The microstructure consists of only ferrite grains (crystals) and grain boundaries. The second example is a microstructure of a low-carbon steel containing 0.02% C in Fig. 3b. In this microstructure, cementite can be seen as particles at the ferrite grain boundaries. The excess carbon rejected from the solid solution of ferrite formed this cementite. As the carbon content in steel is increased, another form of cementite appears as a constituent called pearlite, which can be found in most carbon steels. Examples of pearlite in low-carbon (0.08% C) and medium-carbon (0.20% C) steels are seen in Figs. 4a and 4b. Pearlite has a lamellar (parallel plates) microstructure as shown at higher magnification in Fig. 5 and consists of layers of ferrite and cementite. Thus, in these examples, in increasing the carbon level from 0.002 to 0.02 to

0.08 to 0.20%, the excess carbon is manifested as a carbide phase in two different forms, cementite particles and cementite in pearlite. Both forms increase the hardness and strength of iron. However, there is a trade-off, cementite also decreases ductility and toughness.

Pearlite forms on cooling austenite through a eutectoid reaction as seen below:

A *eutectoid* reaction occurs when a solid phase or constituent reacts to form two different solid constituents on cooling (a *eutectic* reaction occurs when a liquid phase reacts to form two solid phases). The eutectoid reaction is reversible on heating. In steel, the eutectoid reaction (under equilibrium conditions) takes place at 727°C and can be seen on the iron–carbon diagram (Fig. 1) as the “V” at the bottom left side of the diagram. A fully pearlitic microstructure forms at 0.77% C at the eutectoid temperature of 727°C (the horizontal line on the left side of the iron–carbon diagram). Steels with less than 0.77% C are called *hypoeutectoid* steels and consist of mixtures of ferrite and pearlite with the amount of pearlite increasing as the carbon content increases. The ferrite phase is called a *proeutectoid* phase because it forms prior to the eutectoid transformation that occurs at 727°C. A typical example of proeutectoid ferrite is shown in Fig. 6. In this photomicrograph, the ferrite (the white appearing constitu-

**Fig. 6** Photomicrograph of a medium-carbon hypoeutectoid steel showing a pearlite matrix and proeutectoid ferrite nucleating on the original (prior) austenite grain boundaries. 200X. 4% picral + 2% nital etch.

ent) formed on the prior austenite grain boundaries of hypoeutectoid steel with 0.60% C. The remaining constituent (dark appearing) is pearlite. Steels between 0.77% C and about 2% C are called *hypereutectoid* steels and consist of pearlite with proeutectoid cementite. Cementite forms a continuous carbide network at the boundaries of the prior austenite grains. Because there is a carbide network, hypereutectoid steels are characterized as steels with little or no ductility and very poor toughness. This means that in the commercial world the vast majority of carbon steels are hypoeutectoid steels.

Thus, according to the iron–carbon diagram, steels that are processed under equilibrium or near-equilibrium conditions can form (a) pure ferrite at very low carbon levels generally under 0.005% C, (b) ferrite plus cementite particles at slightly higher carbon levels between 0.005% C and 0.022% C, (c) ferrite plus pearlite mixtures between 0.022% C and 0.77% C, (d) 100% pearlite at 0.77% C, and (e) mixtures of pearlite plus cementite networks between 0.77% C and 2% C. The higher the percentage of cementite, the higher the hardness and strength and lower the ductility and toughness of the steel.

***Departure from Equilibrium (Real World).*** Industrial processes do not occur at equilibrium, and only those processes that take place at extremely slow heating and cooling rates can be considered near equilibrium, and these processes are quite rare. Therefore, under real conditions, the iron–carbon diagram can only be used as a rough guideline since the equilibrium transformation

temperatures shift to lower temperatures on cooling and to higher temperatures on heating. If steels are cooled at very fast rates, e.g., quenching in water, the iron–carbon diagram can no longer be used since there is a major departure from equilibrium. In fact, during the quenching of steel, new constituents form that are not associated with the iron–carbon diagram. Therefore, at fast cooling rates the concept of time–temperature transformation (TTT) diagrams must be considered. These diagrams are constructed under isothermal (constant) temperature (called IT diagrams) or continuous-cooling conditions (called CT diagrams). It is important to know how these diagrams are constructed so that we can understand the development of nonequilibrium microstructures, which are so important in carbon and alloy steels.

***Isothermal Transformation Diagram.*** This diagram is formed by quenching very thin specimens of steel in salt baths set at various temperatures. For example, thin specimens of 0.79% C steel can be quenched into seven different liquid salt baths set at 650, 600, 550, 500, 450, 400, and 200°C. The specimens are held for various times at each temperature then pulled from the bath and quickly quenched in cold water. The result will be a diagram called an isothermal transformation (IT) diagram, as shown in Fig. 7. The diagram is essentially a map showing where various constituents form. For example, at 650°C, austenite (A) begins to transform to pearlite if held in the bath for 10 s. The curve drawn through this point is the pearlite transformation start temperature and is labeled beginning of transformation in Fig. 7. At about 100 s the pearlite transformation is finished. The second curve represents the pearlite transformation finish temperature and is labeled the end of transformation in Fig. 7. In this steel, pearlite forms at all temperatures along the start of transformation curve from 727°C (the equilibrium temperature of the iron–carbon diagram) to 540°C, the “nose” of the curve. At the higher transformation temperatures, the pearlite interlamellar spacing (the spacing between cementite plates) is very coarse and decreases in spacing as the temperature is decreased, i.e., nose of the IT diagram is approached. This is an important concept since a steel with a coarse pearlite interlamellar spacing is softer and of lower strength than a steel with a fine pearlite interlamellar spacing. Commercially, rail steels are produced with a pearlitic microstructure, and it has been found that the finer the interlamellar spacing the harder the rail and the better the wear resistance. This means that rails will last longer in track if produced with the finest spacing allowable. Most rail producers employ an accelerated cooling process called head hardening to obtain the necessary conditions to achieve the finest pearlite spacing in the rail head (the point of wheel contact).

If the specimens are quenched to 450°C and held for various times, pearlite does not form. In fact, pearlite does not isothermally transform at transformation temperatures (in this case, salt pot temperatures) below the nose of the diagram in Fig. 7. The new constituent is called bainite, which consists of ferrite laths with small cementite particles (also called precipitates). An example of the microstructure of bainite is shown in Fig. 8. This form of bainite is called upper bainite because it is formed in the upper portion below the nose of the IT diagram (between about 540 and 400°C). Lower bainite, a finer ferrite–carbide

**Fig. 7** Isothermal transformation (IT) diagram of SAE/AISI 1080 steel showing the beginning and end of transformation curves with temperature and time. (Source: *ASM Handbook, Vol. 1, Properties and Selection: Irons, Steels, and High-Performance Alloys*, ASM International, Materials Park, OH 44073-0002, 1990, p. 128.)

microstructure, forms at lower temperatures (between 400 and about 250°C). Bainite is an important constituent is tough, high-strength, low-alloy steel.

If specimens are quenched into a salt bath at 200°C, a new constituent called martensite will form. The start of the martensitic transformation is shown in Fig. 7 as  $M_s$  (at 220°C). Martensite is a form of ferrite that is supersaturated with carbon. In other words, because of the very fast cooling rate, the carbon atoms do not have time to diffuse from their interstitial positions in the bcc lattice to form cementite particles. An example of martensite is shown in Fig. 9. Steel products produced with an as-quenched martensitic microstructure are very hard and brittle, e.g., a razor blade. Most martensitic products are tempered by heating to temperatures between about 350 and 650°C. The tempering process allows some of the carbon to diffuse and form as a carbide phase from the supersaturated iron lattice. This softens the steel and provides some ductility. The degree of softening is determined by the tempering temperature and the time at the tempering temperature. The higher the temperature and the longer the time the softer the steel. Most steels with martensite are used in the quenched and tempered condition.

**Fig. 8** Photomicrograph of a low-alloy steel showing a bainitic microstructure. 500X. 4% picral + 2% nital etch.

**Fig. 9** Photomicrograph of a low-alloy steel showing a martensitic microstructure. 1000X. 4% picral + HCl and 10% sodium metabisulfate etch.

**Continuous-Cooling Transformation Diagram.** The other more useful form of a time–temperature transformation diagram is the continuous-cooling transformation (CT) diagram. This differs from the IT diagram in that it is constructed by cooling small specimens at various cooling rates and measuring the temperatures at which transformations start and finish using a device called a dilatometer (a machine that measures dilation). Each phase transformation undergoes a distinct volume change (positive on cooling and negative on heating) that can be measured by a sensitive length-measuring device in the dilatometer. A CT diagram has similar features to the IT diagram shown in Fig. 7 but is produced by continuous cooling rather than isothermal conditions. A continuous-cooling diagram is applicable for most industrial processes and should be used in lieu of an IT diagram. A CT diagram can also be constructed by quenching one end of a Jominy bar described below.

**Hardenability Concept.** In thick products, e.g., large-diameter bars, thick plate, and heavy forgings, the through-thickness properties are achieved through hardenability. Hardenability is the ability to induce depth of hardness in a steel product. The hardness level is obtained by controlling the amount of martensite in the microstructure. To increase the depth of hardness, certain alloying elements are added to the steel for increased hardenability. Elements, such as nickel, chromium, and molybdenum, shift the pearlite nose of the IT and CT diagrams to the right (longer times). With the nose out of the way on cooling, martensite can formed over a wider range of cooling rates when compared with a steel without alloying elements.

There is a fairly simple test to measure the hardenability of steel called the Jominy test. A 24.4-mm-diameter and 102-mm-long bar is austenitized to 845°C for 1 h and then water quenched at one end of the bar. The quenching takes place in a specially designed fixture where the bar is suspended in the vertical position and water is directed against the machined bottom end face of the bar. After quenching, parallel flats 0.38 mm deep are machined on opposite sides of the bar. Hardness is measured at 1.6-mm ( $\frac{1}{16}$ -in.) intervals from the quenched end. The hardness is plotted against depth from the quenched end to produce a hardenability curve or band. A hardenability band for medium-carbon SAE/AISI 1045 steel is shown in Fig. 10a. The two curves that form the band represent the maximum and minimum hardness values from many Jominy tests. To illustrate the concept of hardenability, compare the hardenability band for SAE/AISI 1045 steel to low-alloy SAE/AISI 4145 steel in Fig. 10b. These steels are similar except that the low-alloy steel has chromium and molybdenum additions as shown below:

| C         | Mn        | Si        | Cr        | Mo        |
|-----------|-----------|-----------|-----------|-----------|
| 0.42/0.51 | 0.50/1.00 | 0.15/0.35 | —         | —         |
| 0.42/0.49 | 0.65/1.10 | 0.15/0.35 | 0.75/1.20 | 0.15/0.25 |

As can be seen from the hardenability bands, the higher manganese, chromium, and molybdenum additions in the SAE/AISI 4145 steel produced a much greater depth of hardness than the plain-carbon steel. For example, a hardness of HRC

Heat-treating temperatures recommended by SAE  
 Normalize (for forged or rolled specimens only): 870 °C (1600 °F)  
 Austenitize: 845 °C (1550 °F)

(a)

**Fig. 10** Hardenability curves (a) SAE/AISI 1045 and (b) SAE/AISI 4145 showing depth of hardness with distance from the quenched end of a Jominy bar (Source: ASM Handbook, Vol. 1, Properties and Selection: Irons, Steels, and High-Performance Alloys, ASM International, Materials Park, OH 44073-0002, 1997, p. 487.)

45 (Rockwell C scale) was achieved at a depth of only 3–6.5 mm in the SAE/AISI 1045 steel compared with a hardness of HRC 45 at a depth of 21–50 mm in the SAE/AISI 4145 steel. This low-alloy steel has many times the depth of hardness or hardenability of the plain-carbon steel. This means that a hardness of HRC 45 can be achieved in the center of a 100-mm-diameter bar of SAE/AISI 4145 steel compared to a 10-mm-diameter bar of SAE/AISI 1045 steel (both water quenched). The depth of hardness is produced by forming martensite near the quenched end of the bar with mixtures of martensite and bainite further in from the end and eventually bainite at the maximum depth of hardness. Hardenability is important since hardness is roughly proportional to tensile strength. To convert hardness to an approximate tensile strength the conversion table in ASTM E140 can be used. A portion of this table is

| 60               | 697     | (654)                | —                              |
| 55               | 595     | 560                  | 2075                           |
| 50               | 513     | 481                  | 1760                           |
| 45               | 446     | 421                  | 1480                           |
| 40               | 392     | 371                  | 1250                           |
| 35               | 345     | 327                  | 1080                           |
| 30               | 302     | 286                  | 950                            |
| 25               | 266     | 253                  | 840                            |

This table also lists Vickers and Brinell hardness values, which are different types of hardness tests. It can be seen that a hardness of HRC 45 converts to an approximate tensile strength of 1480 MPa.

## 4 ROLE OF ALLOYING ELEMENTS IN STEEL

In the hardenability concept described in the previous section, alloying elements have a profound effect on depth of hardness. Alloying elements also change the characteristics of the iron–carbon diagram. For example, in the iron–carbon diagram (see Fig. 1) austenite cannot exist below the eutectoid temperature of 727°C. However, there are steels where austenite is the stable phase at room temperature, e.g., austenitic stainless steels and austenitic manganese steels. This can only be achieved through alloying. There are, however, special conditions where small amounts of austenite can be retained at room temperature during rapid quenching of low alloy steel. When this occurs, the austenite is too rich in alloying elements to transform at room temperature and is thus retained as small regions in a martensitic microstructure. Because of this, it is called retained austenite. The retained austenite can be transformed through tempering the steel.

In austenitic stainless steels, when nickel is added with chromium, the austenite phase field is expanded allowing austenite to be stable at room temperature. The popular SAE/AISI 304 austenitic stainless steel contains 18% Cr and 8% Ni. Austenitic manganese steel (Hadfield steel) contains 12% Mn with 1% C. The Mn and C allow austenite to be stable at room temperature. Because of this ability, nickel and manganese are, therefore, called austenite stabilizers. Other elements are ferrite stabilizers, e.g., chromium, silicon, and molybdenum. A ferrite-stabilizing element expands the ferrite phase field, and the austenite phase field is restricted within what is called a gamma loop (gamma,  $\gamma$ , is the symbol for austenite). A gamma loop can be seen in the iron–chromium equilibrium diagram in Fig. 11. The gamma loop is shown at the left side of the diagram. According to this diagram, iron–chromium alloys with 12.7% Cr or higher, the transformation from austenite ( $\gamma$ ) to ferrite ( $\alpha$ ) does not occur and ferrite exists from room temperature to melting. Iron–chromium alloys make up an important class of stainless steels called ferritic and martensitic stainless steels.

Each particular alloying element has an influence on the structure and properties of steel. The following elements are important alloying elements in steel:

**Carbon.** Carbon is the most common alloying element in steel. It is inexpensive and has a strong influence on hardness and strength. It is the basic and essential alloying element in all plain-carbon, low-alloy, and tool steels. Carbon is an interstitial element that occupies sites between the larger iron atoms in the bcc and fcc lattices. The influence of carbon on the strength of iron can be seen in Fig. 12. Carbon can increase yield strength of pure iron (0% C) with a strength of about 28 to 190 MPa at 0.005% C, the maximum solubility of carbon at room temperature. This sevenfold increase in strength is due to interstitial solid solution strengthening. Any excess carbon, above 0.005% C, will form a iron carbide compound called cementite ( $\text{Fe}_3\text{C}$ ). Cementite can exist as a particle, as a component of lamellar pearlite or as a proeutectoid network on prior austenite grain boundaries in hypereutectoid steel. Thus, carbon in the form of cementite has a further influence on the strength of steel, as seen in Fig. 13. In this plot, the steels between 0.1% C and 0.8% C contain about 10–100% pearlite. Yield strength peaks at about 425 MPa at 0.6% C whereas tensile strength (ultimate strength) increases to 790 MPa at 0.8% C. These properties are for carbon steels in the air-cooled condition. In a 0.8% C steel, a further

**Fig. 11** Iron–chromium equilibrium phase diagram. (Source: *ASM Handbook, Vol. 20, Materials Selection and Design*, ASM International, Materials Park, OH 44073-0002, 1997, p. 365.)

increase in strength can be achieved if faster cooling rates are used to produce a finer pearlite interlamellar spacing. In a fully pearlitic, head-hardened rail steel (accelerated-cooled), the yield strength can increase to 860 MPa and tensile strength to 1070 MPa. Carbon also has a negative effect on properties, as seen in Fig. 13. For example, the percent reduction in area (as well as total elongation not shown) decreases with increasing carbon. The percent reduction in area is a

**Fig. 12** Effect of carbon in solid solution on the yield strength of iron. (Source: *ASM Handbook, Vol. 20, Materials Selection and Design*, ASM International, Materials Park, OH 44073-0002, 1997, p. 367.)

**Fig. 13** Effect of carbon on the tensile and notched impact properties of ferrite-pearlite steels. (Source: ASM Handbook, Vol. 20, *Materials Selection and Design*, ASM International, Materials Park, OH 44073-0002, 1997, p. 367.)

measure of the cross-sectional area change in a tensile specimen before and after fracture. Notch toughness also decreases with carbon content as seen in the decrease in upper shelf energy and the increase in transition temperature. Shelf energy is the upper portion or upper shelf of a curve of absorbed energy plotted from a Charpy test.

**Manganese.** Manganese is also an essential element in all carbon, low-alloy, and alloy steels. Manganese has several roles as an alloying element. One role is to assure that all residual sulfur is combined to form manganese sulfide (MnS). Manganese is generally added to steel with a minimum manganese:sulfur ratio of 20:1. Without manganese the sulfur would combine with iron and form iron sulfide (FeS), which is a brittle compound that lowers toughness and ductility and causes a phenomenon called hot shortness. Hot shortness is a condition where a compound (such as FeS) or insoluble element (such as copper) in steel has a low melting point and thus forms an unacceptable cracklike surface condition during hot rolling. Another role of manganese is in strengthening steel.

Manganese is a substitutional element and can replace iron atoms in the bcc or fcc lattice. Each 0.1% Mn added to iron will increase the yield strength by about 3 MPa. Manganese also lowers the eutectoid transformation temperature and lowers the eutectoid carbon content. In large amounts (12% or higher), manganese is an austenite stabilizer in alloy steels and forms a special class of steels called austenitic manganese steels (also called Hadfield manganese steels). These steels are used in applications requiring excellent wear resistance, e.g., in rock crushers and in railway track connections where two rails meet or cross.

**Silicon.** Silicon is added to many carbon and low-alloy steels as a deoxidizer, i.e., it removes dissolved oxygen from molten steel during the steel-refining process. Oxygen is an undesirable element in steel because it forms oxide inclusions, which can degrade ductility, toughness, and fatigue resistance. Silicon has a moderate effect on strengthening steel but is usually not added for strengthening. Each 0.1% Si increases the yield strength of iron by about 8 MPa. It is a ferrite stabilizer and is found in some stainless steels. Silicon is also added to steel for enhanced electrical properties, e.g., iron–silicon transformer steels at 3.25% Si. These carbon-free steels have high magnetic permeability and low core loss.

**Phosphorus.** Phosphorus is considered a tramp or residual element in steel and is carefully restricted to levels generally below 0.02%. However, like carbon, phosphorus is an interstitial element that can substantially strengthen iron. For this reason, phosphorus is added to a special class of steels called rephosphorized steels for strength. Rephosphorized steels also have enhanced machinability.

**Sulfur.** Sulfur is also considered a tramp element in steel and is usually restricted to below about 0.02%. Although an element with a small atomic diameter, sulfur is not considered an interstitial alloying element because it is insoluble in iron. However, as in the case of phosphorus, sulfur is added to a special class of steels called resulfurized steels that have improved machinability. These steels are called free-machining steels.

**Copper.** In most steels copper is considered a tramp (residual) element and is restricted to levels below 0.04%. Copper, having a much lower melting point than iron, can create a detrimental steel surface condition known as hot shortness. Although not generally added to steel, there is a very special class of steels that contain high levels of copper to take advantage of the precipitation of copper particles during aging (a tempering process). These copper particles increase strength and hardness. Copper is also added to low-alloy steels for atmospheric corrosion protection (these steels are called weathering steels). One problem with copper in steel is that it cannot be oxidized and removed during steel refining. Thus, over time, the copper level of steel produced from steel scrap is slowly increasing.

**Nickel.** Nickel is an important element because of its positive effect on hardenability. Many important low-alloy steels contain nickel for this reason. Nickel, being a substitutional element in the iron lattice has a small effect on increasing yield strength. Nickel, being an austenite stabilizer, is also a vital

element in austenitic stainless steels. Nickel is also important in steels for cryogenic applications, storage tanks for liquefied hydrocarbon gases. Nickel does not form a carbide and remains in solid solution.

**Chromium.** Like nickel, chromium has a positive effect on hardenability and is an important alloying element in many low-alloy steels. For corrosion resistance, chromium is present in all stainless steels as a solid solution element. In addition to hardenability and solid solution effects, chromium forms several important chromium carbides that are necessary for wear resistance in many tool steels and steels used for rolls in hot- and cold-rolling mills.

**Molybdenum.** Molybdenum is a potent hardenability element and is found in many low-alloy steels. Molybdenum, like chromium, forms several types of carbides that are important for wear-resistant applications, e.g., tool steels. Molybdenum is added to minimize temper embrittlement in low-alloy steels. Temper embrittlement occurs when low-alloy steels are tempered in the temperature range of 260–370°C. The embrittlement is caused by tramp elements such as phosphorus that accumulate at the prior austenite grain boundaries and thus weaken the boundaries. Adding molybdenum prevents the accumulation of these undesirable elements at the boundaries. Molybdenum also enhances the creep strength of low-alloy steels at elevated temperatures and is used in rotors and other parts of generators in electric power plants. Creep is an undesirable process that allows steel to slowly elongate or creep under load. Eventually the component will fail.

**Vanadium.** Although vanadium is a potent hardenability element, its most useful role is in the formation of a vanadium nitride and vanadium carbide (it can also be in a combined form of vanadium carbonitride). A very important role of vanadium is in microalloyed steels, also called high-strength, low-alloy (HSLA) steels. These steels are strengthened by precipitation of vanadium nitrides and vanadium carbides (vanadium carbonitrides). The formation of vanadium carbide is important for wear resistance. Vanadium carbide is much harder than iron carbide, chromium carbide, and molybdenum carbide. Vanadium is thus important in high-speed tool steels, which are used as drill bits that retain their hardness as the tool heats by friction.

**Tungsten.** Tungsten is not an addition to low-alloy steels but is a vital alloying element in high-speed tool steels where it forms hard tungsten carbide particles.

**Aluminum.** Aluminum is employed as a deoxidizer in steel and is generally used in conjunction with silicon (also a deoxidizer). A deoxidizer removes undesirable oxygen from molten steel. Once removed, the steel is called “killed.” Aluminum–silicon deoxidized (killed) steels are known as fine-grain steels. Another important role of aluminum is the formation of an aluminum nitride (AlN) precipitate. Many steels depend upon the formation of AlN, especially steels used for sheet-forming applications requiring a high degree of formability such as parts that require deep drawing. These steels are called drawing-quality special-killed (DQSK) steels. The AlN precipitates help in the formation of an

optimum crystallographic texture (preferred orientation) in low-carbon sheet steels for these deep-drawing applications. When aluminum combines with nitrogen to form AlN, the dissolved interstitial nitrogen is lowered. Lower interstitial nitrogen (interstitial nitrogen is also called free nitrogen) provides improved ductility. Aluminum can also substitute for silicon in electrical steels for laminations in electric motors and transformer cores.

**Titanium.** Titanium is a strong deoxidizer but is usually not used solely for that purpose. Titanium is important in microalloyed steels (HSLA steels) because of the formation of titanium nitride (TiN) precipitates. Titanium nitrides pin grain boundary movement in austenite and thus provides grain refinement. Another role of titanium is in steels containing boron where a titanium addition extracts nitrogen from liquid steel so that boron, a strong nitride former, remains in elemental form to enhance hardenability. Because of its affinity for both carbon and nitrogen, titanium is important in interstitial-free (IF) steels. Interstitial-free steels are an important class of steels with exceptional formability. Titanium, being a strong carbide former, is used as a carbide stabilizer in austenitic stainless steels (AISI type 321), ferritic stainless steels (AISI type 409, 439, and 444), and precipitation hardening stainless steels (AISI type 600 and 635).

**Niobium (Columbium).** Niobium is also important in microalloyed (HSLA) steels for its precipitation strengthening through the formation of niobium carbonitrides. Some microalloyed steels employ both vanadium and niobium. Because of its affinity for both carbon and nitrogen, niobium is an element found in some IF steels. Niobium is also added as a carbide stabilizer (prevents carbides from dissolving and reforming in undesirable locations) in some austenitic stainless steels (AISI type 347, 348, and 384), ferritic stainless steels (AISI type 436 and 444), and precipitation hardening stainless steels (AISI type 630).

**Tantalum.** Because of its affinity for carbon, tantalum, like niobium, is added as a carbide stabilizer to some austenitic stainless steels (AISI type 347 and 348).

**Boron.** On a weight percent basis, boron is the most powerful hardenability element in steel. A minute quantity of boron, e.g., 0.003%, is sufficient to provide ample hardenability in a low-alloy steel. However, boron is a strong nitride former and can only achieve its hardenability capability if in elemental form. Thus, boron must be protected from forming nitrides by adding a sufficient amount of titanium to first combine with the nitrogen in the steel.

**Calcium.** Calcium is a strong deoxidizer in steel but is not used for that purpose. In a aluminum-deoxidized (killed) steel, calcium combines with sulfur to form calcium sulfide particles. This form of sulfide remains as spherical particles as compared with manganese sulfide, which is soft and elongates into stringers upon hot rolling. Thus, steels properly treated with calcium do not have the characteristics associated with MnS stringers, i.e., property directionality or anisotropy.

**Zirconium.** Although expensive and rarely added to steel, zirconium acts like titanium in forming zirconium nitride precipitates.

**Nitrogen.** Nitrogen is added to some steels, e.g., steels containing vanadium, to provide sufficient nitrogen for nitride formation. This is important in microalloyed steels containing vanadium. Nitrogen, being an interstitial element like carbon, strengthens ferrite. A number of austenitic stainless steels contain nitrogen for strengthening (AISI type 201, 202, 205, 304N, 304LN, 316N, and 316LN).

**Lead.** Lead is added to steel for enhanced machinability. Being insoluble in iron, lead particles are distributed through the steel and provide both lubrication and chip breaking ability during machining. However, leaded steels are being discontinued around the world because of the environmental health problems associated with lead.

**Selenium.** Selenium is added to some austenitic stainless steels (AISI type 303Se), ferritic stainless steels (AISI type 430Se), and martensitic stainless steels (AISI type 416Se) for improved machined surfaces.

**Rare Earth Elements.** The rare earth elements cerium and lanthanum are added to steel for sulfide shape control, i.e., the sulfides become rounded instead of stringers. It is usually added in the form of mish metal (a metallic mixture of the rare earth elements).

**Residual Elements.** Tin, antimony, arsenic, and copper are considered residual elements in steel. They are also called tramp elements. These elements are not intentionally added to steel but remain in steel because they are difficult to remove during steelmaking and refining. Steels made by electric furnace melting employing scrap as a raw material contain higher levels of residual elements than steels made in an integrated steelmaking facility (blast furnace–BOF route). Some electric furnace melting shops use direct-reduced iron pellets to dilute the effect of these residuals.

**Hydrogen.** Hydrogen gas is also a residual element in steel and can be very deleterious. Hydrogen is soluble in liquid steel and somewhat soluble in austenite. However, it is very insoluble in ferrite and is rejected as atomic hydrogen ( $H^+$ ). If trapped inside the steel, usually in products such as thick plate, heavy forgings, or railroad rail, hydrogen will accumulate on the surfaces of manganese sulfide inclusions. When this accumulation takes place, molecular hydrogen ( $H_2$ ) can form and develop sufficient pressure to create internal cracks. As the cracks grow, they form what is termed hydrogen flakes and the product must be scrapped. However, if the product is slowly cooled from the rolling temperature, the atomic hydrogen has sufficient time to diffuse from the product thus avoiding hydrogen damage. Also, most modern steelmakers use degassing to remove hydrogen from liquid steel.

## 5 HEAT TREATMENT OF STEEL

One of the very important characteristics of steel is the ability to alter the microstructure through heat treatment. As seen in the previous sections, many different microstructural constituents can be produced. Each constituent imparts a particular set of properties to the final product. For example, by quenching a steel in water, the steel becomes very hard but brittle through the formation of

martensite. By tempering the quenched steel, some ductility can be restored with some sacrifice in hardness and strength. Also, superior wear properties can be obtained in fully pearlitic microstructures, particularly if an accelerated cooling process is employed to develop a fine interlamellar spacing. Complex parts can be designed by taking advantage of the formability and ductility of ferritic sheet steel through cold rolling and annealing. The amount of pearlite in ferritic steel can be adjusted by carbon content and cooling rate to produce a wide range of hardness and strength. In quenched and tempered steels, a bainitic microstructure has a unique combination of high strength and toughness. Thus steel, more than any other metallic material, can be manipulated through heat treatment to provide a multiplicity of microstructures and final properties. The common types of heat treatment are listed below:

**Annealing (Full Annealing).** One of the most common heat treatments for steel is annealing. It is used to soften steel and to improve ductility. In this process, the steel is heated into the lower regions of the austenite phase field and slow cooled to room temperature. The resulting microstructure consists of coarse ferrite or coarse ferrite plus pearlite, depending upon carbon and alloy content of the steel.

**Normalizing.** Steel is normalized by heating into the austenite phase field at temperatures somewhat higher than those used by annealing followed by air cooling. Many steels are normalized to establish a uniform ferrite plus pearlite microstructure and a uniform grain size.

**Spheroidizing.** To produce a steel in its softest possible condition, it is usually spheroidized by heating just above or just below the eutectoid temperature of  $727^{\circ}\text{C}$  and holding at that temperature for an extended time. This process breaks down lamellar pearlite into small spheroids of cementite in a continuous matrix of ferrite as seen in Fig. 14. To obtain a very uniform dispersion of cementite spheroids, the starting microstructure is usually martensite. This is because carbon is more uniformly distributed in martensite than in lamellar pearlite. The cementite lamella must first dissolve and then redistribute the carbon as spheroids whereas the cementite spheroids can form directly from martensite.

**Process Annealing (Recrystallization Annealing).** Process annealing takes place at temperatures just below the eutectoid temperature of  $727^{\circ}\text{C}$ . This treatment is applied to low-carbon, cold-rolled sheet steels to restore ductility. In aluminum-killed steels, the recrystallized ferrite will have an ideal crystallographic texture (preferred orientation) for deep drawing into complex shapes such as oil filter cans and compressor housings. Crystallographic texture is produced by developing a preferred orientation of the ferrite grains, i.e., the crystal axes of the ferrite grains are oriented in a preferred rather than random orientation.

**Stress Relieving.** Steel products with residual stresses can be heated to temperatures approaching the eutectoid transformation temperature of  $727^{\circ}\text{C}$  to relieve the stress.

**Fig. 14** Photomicrograph of a medium-carbon steel in the spheroidized condition. 500X. 4% picral + 2% nital etch.

**Quenching.** To produce the higher strength constituents of bainite and martensite, the steel must be heated into the austenite phase field and rapidly cooled by quenching in oil or water. High-strength, low-alloy (HSLA) steels are produced by this process followed by tempering. It must be noted that employing microalloying additions such as Nb, V, and Ti can also produce HSLA steels. These microalloyed steels obtain their strength by thermomechanical treatment rather than heat treatment.

**Tempering.** When quenched steels (martensitic steel) are tempered by heating to temperatures approaching the eutectoid temperature of 727°C, the dissolved carbon in the martensite forms cementite particles, and the steels become more ductile. Quenching and tempering are used in a variety of steel products to obtain desired combinations of strength and toughness.

## 6 CLASSIFICATION AND SPECIFICATIONS OF STEELS

Since there are literally thousands of different steels, it is difficult to classify them in a simple straightforward manner. However, some guidelines can be used. For example, steels are generally classified as carbon steel or alloy steel. A classification system was developed by the Society of Automotive Engineers (SAE) as early as 1911 to describe these carbon and alloy steels. The American Iron and Steel Institute (AISI) collaborated with SAE to refine the compositional ranges of the classification that are used today. Recently, a Unified Numbering System (UNS) was established that incorporates the SAE/AISI number.

Many steel products are purchased by specifications describing specific compositional, dimensional, and property requirements. Specification organizations

such as ASTM (American Society for Testing and Materials) have developed numerous specifications for steel products and the testing of steel products. Some specific product user groups in the United States have developed their own specifications, e.g., the American Bureau of Ships (ABS) for ship plate and other marine products, Aerospace Materials Specifications (AMS) for aerospace applications, the American Railway Engineering and Maintenance of Way Association (AREMA) for rail and rail products, the Society of Automotive Engineers (SAE) for automotive applications, and the American Society of Mechanical Engineers (ASME) for steels produced to boiler code specifications. In Japan, there are standards developed by the Japanese Industrial Standards (JIS) Committee of the Ministry of International Trade and Industry. In the United Kingdom, there are the British Standards (BS) developed by the British Standards Institute. In Europe, Germany has the Deutsches Institut für Normung (DIN) standards, France the Association Francaise de Normalisation (AFNOR) standards, and Italy the Ente Nazionale Italiano di Unificazione (UNI) standards.

Specifications can be as simple as a hardness requirement, i.e., ASTM A1 for rail steel to elaborate compositional and property requirements as in ASTM A808 “High-strength low-alloy carbon–manganese–niobium–vanadium steel of structural quality with improved notch toughness.” Describing specific specifications is beyond the scope of this handbook but many of the key sources can be found in the Bibliography at the end of this chapter.

### 6.1 Carbon Steels

Carbon steels (also called plain-carbon steels) constitute a family of iron–carbon–manganese alloys. In the SAE/AISI system, the carbon steels are classified as follows:

|                                        |             |
|----------------------------------------|-------------|
| Nonresulfurized carbon steels          | 10xx series |
| Resulfurized steels                    | 11xx series |
| Rephosphorized and resulfurized steels | 12xx series |
| High manganese carbon steels           | 15xx series |

A four-digit SAE/AISI number is used to classify the carbon steels with the first two digits being the series code and the last two digits being the nominal carbon content in points of carbon (1 point = 0.01% C). For example, SAE/AISI 1020 steel is a carbon steel containing 0.20% C (actually 0.18–0.22% C). The chemical composition limits for the above SAE/AISI 10xx series of carbon steels for semifinished products, forgings, hot- and cold-finished bars, wire, rods, and tubing are listed in *SAE Materials Standards Manual* (SAE HS-30, 1996). There are slight compositional variations for structural shapes, plates, strip, sheet, and welded tubing (see SAE specification J403). The *SAE Manual* gives the SAE/AISI number along with the UNS number. The carbon level spans the range from under 0.06% C to 1.03% C.

Because of the wide range in carbon content, the SAE/AISI 10xx carbon steels are the most commonly used steels in today’s marketplace. All SAE/AISI 10xx series carbon steels contain manganese at levels between 0.25 and 1.00%. For a century, manganese has been an important alloying element in steel because it combines with the impurity sulfur to form manganese sulfide (MnS).

MnS is much less detrimental than iron sulfide (FeS), which would form without manganese present. Manganese sulfides are usually present in plain and low-alloy steels as somewhat innocuous inclusions. The manganese that does not combine with sulfur strengthens the steel. However, with the development of steelmaking practices to produce very low sulfur steel, manganese is becoming less important in this role.

The SAE/AISI 11xx series of resulfurized steels contain between 0.08 and 0.33% sulfur. Although in most steel, sulfur is considered an undesirable impurity and is restricted to less than 0.05%, in the SAE/AISI 11xx and 12xx series of steels, sulfur is added to form excess manganese sulfide inclusions. These are the free-machining steels that have improved machinability over lower sulfur steels due to enhanced chip breaking and lubrication created by the MnS inclusions.

The SAE/AISI 12xx series are also free-machining steels and contain both sulfur (0.16–0.35%) and phosphorus (0.04–0.12%). The SAE/AISI 15xx series contain higher manganese levels (up to 1.65%) than the SAE/AISI 10xx series of carbon steels.

Typical mechanical properties of selected SAE/AISI 10xx and 11xx series of carbon steels are listed in first part of the table on pp. 20–23, Section 4, of the *ASM Metals Handbook*, Desktop Edition, 1985, for four different processing conditions (as-rolled, normalized, annealed, and quenched and tempered). These properties are average properties obtained from many sources, and thus this table should only be used as a guideline. The as-rolled condition represents steel before any heat treatment was applied. Many applications utilize steel in the as-rolled condition. As can be seen from the aforementioned ASM table, yield and tensile strength is greater for steel in the normalized condition. This is because normalizing develops a finer ferrite grain size. Yield and tensile strength is lowest for steels in the annealed condition. This is due to a coarser grain size developed by the slow cooling rate from the annealing temperature. In general, as yield and tensile strength increase, the percent elongation decreases. For example, in the ASM table, annealed SAE/AISI 1080 steel has a tensile strength of 615 MPa and a total elongation of 24.7% compared with the same steel in the normalized condition with a tensile strength of 1010 MPa and a total elongation of 10%. This relationship holds for most steel.

### **Special Low-Carbon Steels**

These are the steels that are not classified in the aforementioned SAE table or listed in the aforementioned ASM table. As mentioned earlier, carbon is not always beneficial in steels. These are special steels with carbon contents below the lower level of the SAE/AISI 10xx steels. There are a number of steels that are produced with very low carbon levels (less than 0.002% C), and all the remaining free carbon in the steel is tied up as carbides. These steels are known as IF steels, which means that the interstitial elements of carbon and nitrogen are no longer present in elemental form in the iron lattice but are combined with elements such as titanium or niobium as carbides and nitrides (carbonitrides). Interstitial-free steels are required for exceptional formability especially in applications requiring deep drawability. Drawability is a property that allows the steel to be uniformly stretched (or drawn) in thickness in a closed die without

localized thinning and necking (cracking or breaking). An example of a deep-drawn part would be a compressor housing for a refrigerator. With proper heat treatment, IF steels develop a preferred crystallographic orientation that favors a high plastic anisotropy ratio or  $r$  value. High  $r$ -value steels have excellent deep drawing ability and these steels can form difficult parts. Another type of low-carbon steel is a special class called deep-quality special-killed (DQSK) steel. This type of aluminum-treated steel also has a preferred orientation and high  $r$  value. The preferred orientation is produced by hot rolling the steel on a hot strip mill followed by rapid cooling. The rapid cooling keeps the aluminum and interstitial elements from forming aluminum nitride particles (i.e., the Al and N atoms are in solid solution in the iron lattice). After rolling, the steel is annealed to allow aluminum nitride to precipitate. The aluminum nitride plays an important role in the development of the optimum crystallographic texture. DQSK steel is used in deep-drawing applications that are not as demanding as those requiring IF steel.

A new family of steels called bake-hardening steels also have a low, but controlled carbon content. These steels gain strength during the paint-bake cycle of automotive production. Controlled amounts of both carbon and nitrogen combine with carbonitride-forming elements such as titanium and niobium during the baking cycle (generally 175°C for 30 min). The precipitation of these carbonitrides during the paint-bake cycle strengthen the steel by a process called aging.

*Enameling steel* is produced with as little carbon as possible because during the enameling process, carbon in the form of carbides can react with the frit (the particles of glasslike material that melts to produce the enamel coating) to cause defects in the coating. Thus, steels to be used for enameling are generally decarburized in a special reducing atmosphere during batch annealing. In this process, the carbon dissipates from the steel. After decarburization, the sheet steel is essentially pure iron. Enamel coatings are used for many household appliances such as washers and dryers, stovetops, ovens, and refrigerators. Also, steel tanks in most hot-water heaters have a glass (or enameled) inside coating.

Electrical steels and motor lamination steels are also produced with as low a carbon content as possible. Dissolved carbon and carbides in these steels are avoided because the magnetic properties are degraded. The carbides, if present in the steel, inhibit the movement of the magnetic domains and lower the electrical efficiency. These steels are used in applications employing alternating current (AC) in transformers and electric motors. Most electric motors for appliances and other applications have sheet steel stacked in layers (called laminations) that are wound in copper wire. Electrical steels used for transformers contain silicon, which is added to enhance the development of a specific crystallographic orientation that favors electrical efficiency.

## 6.2 Alloy Steels

Alloy steels are alloys of iron with the addition of one or more of the following elements; carbon, manganese, silicon, nickel, chromium, molybdenum, and vanadium. The alloy steels cover a wide range of steels including low-alloy steels, stainless steels, heat-resistant steels, and tool steels. Some alloy steels, such as austenitic stainless steels, do not contain intentional additions of carbon. Silicon,

when required, is added as a deoxidizer to the molten steel. Nickel provides strength and assists in hardening the steel by quenching and tempering heat treatment. This latter effect is called hardenability, which has been described earlier. Chromium is found in stainless steels for corrosion resistance. Chromium and molybdenum also assist in hardenability of the low-alloy steels. Vanadium strengthens the steel by forming precipitates of vanadium carbonitride. Vanadium is also a potent hardenability element.

### Low-Alloy Steels

There is an SAE/AISI four-digit classification system for the low-alloy steels. As in the carbon steels, the first two digits are for the alloy class and the last two (or three digits) are for the carbon content. Because of the various combinations of elements, the system is more extensive than that used for the carbon steels. The general SAE/AISI classification system for low-alloy steels is as follows:

|                                   |                                                                                                |
|-----------------------------------|------------------------------------------------------------------------------------------------|
| Manganese steels                  | 13xx series                                                                                    |
| Nickel steels                     | 23xx, 25xx series                                                                              |
| Nickel–chromium steels            | 31xx, 32xx, 33xx, and 34xx series                                                              |
| Molybdenum steels                 | 40xx, 44xx series                                                                              |
| Chromium–molybdenum steels        | 41xx series                                                                                    |
| Nickel–chromium–molybdenum steels | 43xx and 47xx series<br>81xx, 86xx, 87xx, and 88xx series<br>93xx, 94xx, 97xx, and 98xx series |

| Chromium steels                   | 50xx and 51xx series<br>50xxx, 51xxx, and 52xxx series                                         |
| Chromium–vanadium steels          | 61xx series                                                                                    |
| Tungsten–chromium steels          | 71xxx, 72xx series                                                                             |
| Silicon–manganese steels          | 92xx                                                                                           |
| Boron steels                      | xxBxx series                                                                                   |
| Leaded steels                     | xxLxx series                                                                                   |

The boron-containing steels are low-alloy steels with boron added in the amount of 0.0005–0.003%. Boron is a strong hardenability element. The leaded steels contain 0.15–0.35% lead for improved machinability (however, lead is no longer favored as an alloying addition because of health concerns).

A table in the aforementioned SAE HS-30 lists the composition limits of most of the families of the SAE/AISI low-alloy steels listed above. These steels are supplied in the form of bar, plate, and forged products and are usually heat treated to obtain specific mechanical properties, especially high strength and toughness. Mechanical properties of selected SAE/AISI low-alloy steels in the as-rolled, annealed, normalized and quenched and tempered conditions are listed in the aforementioned ASM table. These properties are average properties and should only be used as a guideline. For example, SAE/AISI 4340 steel is usu-

ally heat treated by heating the component to 950–1000°C followed by quenching in oil. The component is then tempered at a temperature between 205–650°C. According to the aforementioned ASM table, this nickel–chromium–molybdenum steel in the quenched and tempered condition (tempered at 205°C) can achieve a yield strength of 1675 MPa and a tensile strength of 1875 MPa. Quenched and tempered low-alloy steels are used in a large number of applications requiring high strength and good toughness. Note that in the annealed condition, SAE/AISI 4340 steel has a yield strength of only 745 MPa.

### **Other Low-Alloy Steels**

There are a number of important steels that do not fit into the SAE/AISI classification system described above. Such classes are the microalloyed steels also called high-strength, low-alloy (HSLA) steels, dual-phase steels, trip steels, and high-performance steels.

***Microalloyed (High-Strength, Low-Alloy) Steels.*** Microalloying is a term applied to steels that contain small additions of alloying elements that retard austenite recrystallization and pin austenite grain boundary movement by the formation of small carbide and/or nitride precipitates. These elements include vanadium, niobium, and titanium. These HSLA steels are produced for a variety of plates, structural shapes, bars, and sheet applications with yield strength varying from 290 to 690 MPa. These steels are covered under numerous SAE and ASTM specifications. The SAE high-strength, low-alloy steels are covered under specifications J410, J1392, and J1442 and the ASTM high-strength, low-alloy steels are covered under various specifications including A242, A440, A441, A572, A588, A606, A607, A618, A633, A656, A690, A709, A714, A715, A808, A812, A841, A860, and A871. These HSLA steels have found wide application in areas such as bridge construction (structural beams), off-shore oil and natural gas platforms, ship hull and deck plate, and electrical transmission towers and poles. In the automobile, HSLA steels are used for safety (ultrahigh-strength impact door beams and energy-absorbing bumper assemblies) and for increasing fuel economy through thinner (lighter weight) chassis structural sections. Microalloyed HSLA steels are also employed in large-diameter gas transmission pipelines.

***Dual-Phase Steels.*** A relatively recent development, dual-phase steels are produced by rapidly cooling a medium-carbon steel, containing vanadium or molybdenum, from the two-phase ferrite plus austenite region. The austenite transforms into islands of martensite (stabilized at room temperature by the V and Mo additions) in a ferrite matrix. Depending upon the alloy content, the martensite islands can also contain austenite that is retained below the transformation temperature (called retained austenite). Thus, dual-phase steel may contain both martensite and austenite as a second phase (called MA constituent). The unique characteristic of dual-phase steels is the continuous yielding behavior during deformation; i.e., there is a lack of a yield point during deformation. This provides increased uniform elongation and work hardening so that those components or parts produced from dual-phase steel actually gain strength during the forming operation. Dual-phase steels are being applied in applications such

as automobile wheel rims and wheel disks. Because of their energy-absorbing characteristics, dual-phase steels are being used in critical locations of the automobile for safety to protect the occupants in the event of a crash.

**Trip Steels.** Similar to dual-phase steels, trip steels have emerged as an energy-absorbing high-strength steel for the automobile. The term “trip” is derived from the mechanism of *transformation induced plasticity*. These steels contain a high percentage of retained austenite (10–15%). The austenite transforms to martensite during the forming of the part, thus providing enhanced formability or transforms upon impact in a crash.

**High-Performance Steels.** There are a number of high-performance steels that are used in critical applications. These low-alloy steels, such as HY80 and HY100, are used in applications requiring high strength and excellent toughness. The “80” and “100” in the codes represents the minimum yield strength in ksi units. Another family of low-alloy steels is used in heat exchangers, high-temperature piping, and boiler applications. These steels like 2¼% Cr–1% Mo find wide use in these applications. Other high-performance steels are the Ni–Cr–Mo steels used as rotors for large steam generators and motors in electric power plants. These steels must withstand temperatures of superheated steam and must maintain high strength, superior toughness, as well as high fatigue strength and creep resistance. Ni–Cr–Mo–V steels are also used in pressure vessels in nuclear reactors.

## Higher Alloy Steels

There is a distinction between the low-alloy steels described above and the higher alloy steels (usually containing over 8% alloying elements). The higher alloy steels include stainless steels, tool steels, heat-resistant steels, wear-resistant steels, and ultrahigh-strength steels.

**Stainless Steels.** Stainless steels are corrosion-resistant steels that contain at least 10.5% chromium. Chromium is unique in that it forms a passive layer on the steel surface that provides protection from corrosion. There are basically five types of stainless steels: austenitic, ferritic, duplex, martensitic, and precipitation hardening steels. These five types of stainless steel have a somewhat simplified classification system as follows:

|                                              |               |
|----------------------------------------------|---------------|
| Austenitic stainless steels with low nickel  | 2xx series    |
| Austenitic stainless steels                  | 3xx series    |
| Ferritic stainless steels                    | 4xx series    |
| Duplex stainless steel                       | 329           |
| Martensitic stainless steels                 | 4xx series    |
| Precipitation strengthening stainless steels | 6xx (xx-x PH) |

The classification system is different for the stainless steels than the system for SAE/AISI low-alloy steels in that the last two digits (xx) do not represent the carbon content and have no particular compositional meaning. Unfortunately,

the classification system has some confusion with the ferritic and martensitic stainless steels both of the 4xx series. The 2xx series of austenitic stainless steels were developed during the 1950s when nickel became scarce. In these steels, manganese and nitrogen were substituted for the lower nickel level in order to maintain strength. Each type of stainless steel is expanded upon below:

*Austenitic Stainless Steels.* Austenitic stainless steels have sufficient alloying to stabilize austenite at room temperature. These steels being austenitic are non-magnetic. Austenitic stainless steels have excellent low-temperature toughness, weldability, and corrosion resistance. On the other hand, they have relatively low yield strength and can only be strengthened by cold working the steel, by precipitation hardening or by interstitial or substitutional solid solution strengthening.

The table on pp. 15.1–15.4 of the *ASM Metals Handbook*, Desktop Edition, 1985, lists the composition limits of the austenitic stainless steels. In general, the 3xx series are iron–chromium–nickel alloys that contain 16–26% chromium and 6–22% nickel. The popular type 304 austenitic stainless steel contains 18–20% Cr and 8–12% Ni and is often referred to as “18–8” stainless steel for the chromium and nickel content. There are many compositional variations of austenitic stainless steel steels. The following list summarizes these variations:

|       |                                                        |
|-------|--------------------------------------------------------|
| 201   | Low nickel replaced with manganese and nitrogen        |
| 202   | Higher Mn than 201                                     |
| 205   | Higher Mn and N than 202                               |
| 301   | Lower Ni and Cr to increase work-hardening ability     |
| 302   | General-purpose 18–8 stainless steel                   |
| 302B  | Scaling resistance improved with Si                    |
| 303   | Enhanced machinability with a S addition               |
| 303Se | Improved machined surfaces with a selenium addition    |
| 304   | Popular 18–8 stainless steel, lower C than 302         |
| 304L  | Low-carbon 304 for improved corrosion resistance       |
| 304LN | Low-carbon 304 with nitrogen added for strength        |
| 304H  | Higher carbon 304                                      |
| 304Cu | Copper added for improved cold working                 |
| 304N  | Nitrogen added for strength                            |
| 305   | Higher Ni for reduced work hardening                   |
| 308   | Higher Cr and Ni for weldability                       |
| 309   | High Cr and Ni for heat resistance                     |
| 309S  | Lower carbon 309                                       |
| 309Cb | Niobium (columbium) added                              |
| 310   | Higher Cr and Ni than 309 for improved heat resistance |
| 310S  | Lower carbon 310                                       |
| 310Cb | Niobium (columbium) added                              |
| 314   | Higher Si for improved heat resistance                 |

|       |                                                             |
|-------|-------------------------------------------------------------|
| 316   | Mo added for improved corrosion resistance                  |
| 316F  | Higher S and P for machinability                            |
| 316L  | Lower C for improved corrosion resistance and weldability   |
| 316LN | Lower C and higher nitrogen (for strength)                  |
| 316H  | Higher carbon 316                                           |
| 316N  | Nitrogen added for strength                                 |
| 316Ti | Titanium added                                              |
| 316Cb | Niobium (columbium) added                                   |
| 317   | Higher Cr and Mo for improved corrosion resistance          |
| 317L  | Low-carbon 317 for improved weldability                     |
| 321   | Titanium added to minimize Cr carbide precipitation         |
| 330   | High Ni to minimize carburization and improve thermal shock |
| 347   | Nb and Ta added to minimize Cr carbide precipitation        |
| 347H  | Higher carbon 347                                           |
| 348   | Ta and Co added for restricted nuclear applications         |
| 348H  | Higher carbon 348                                           |
| 384   | Higher Ni for decreased work hardening                      |

The limiting of carbon is important in austenitic stainless steels. When heated, carbon forms chromium carbide that precipitates on the austenite grain boundaries and produces a condition known as sensitization. Because the chromium is tied-up as carbide, the chromium adjacent to the boundaries will be depleted in chromium and corrosion can take place. Sensitization is reversible by heating the steel to temperatures between 1040 and 1150°C followed by rapid cooling to room temperature. The high temperature dissolves the carbides and the rapid cooling prevents reprecipitation of the carbides. More on austenitic stainless steel can be found in the next chapter.

*Ferritic Stainless Steels.* The ferritic stainless steels are basically iron–chromium alloys with chromium ranging from 10.5 to 27%. The compositional limits for the ferritic stainless steels are listed in the aforementioned ASM table. Nickel is absent in ferritic stainless steels except for minor amounts, i.e., less than 1%, in some alloys. These steels have a microstructure of ferrite at room temperature and are magnetic. Type 409 stainless steel with the lowest chromium level (10.5–11.75%) is the least expensive of the ferritic stainless steel series and is used for automotive exhaust systems because it far outlasts carbon steel in that application. There are fewer variations of ferritic stainless steels than austenitic stainless steels. The ferritic stainless steels are listed below:

|       |                                               |
|-------|-----------------------------------------------|
| 405   | Low Cr with Al added                          |
| 409   | Low Cr, for automotive exhaust applications   |
| 429   |                                               |
| 430   | General-purpose ferritic stainless steel      |
| 430F  | Free machining with higher S and P            |
| 430Se | Selenium added for improved machined surfaces |

|     |                                                                 |
|-----|-----------------------------------------------------------------|
| 434 | Mo added for improved corrosion resistance                      |
| 436 | Mo, Nb, and Ta added for corrosion and heat resistance          |
| 439 | Low C, Ti added to minimize sensitization                       |
| 442 | Higher Cr for improved oxide scaling resistance                 |
| 444 | Low C, Mo for corrosion resistance, Ti and Nb for sensitization |
| 446 | Highest Cr for improved scaling resistance                      |

Ferritic stainless steels are described in more detail in the next chapter.

*Duplex Stainless Steels.* Type 329 is an iron–chromium alloy with 2.5–5% nickel and 1–2% molybdenum that has a mixed (duplex) microstructure of approximately equal percentages of ferrite and austenite. There are many more duplex stainless steels that have priority compositions and trade names (see Bibliography at the end of chapter). The corrosion characteristics of these duplex stainless steels are similar to austenitic stainless steels. However, they have higher strength and better resistance to stress–corrosion cracking than austenitic stainless steels. Duplex stainless steels are discussed in the next chapter.

*Martensitic Stainless Steels.* To produce martensite in a stainless steel, the alloy must be transformed from the austenite phase field. According to the equilibrium phase diagram, this means that they have restricted chromium levels within the range required to form the gamma loop where austenite exists (see Fig. 11). The gamma loop is the region between 800 and 1400°C and 0 and 12.7% Cr in Fig. 11. Since austenite only exists in this restricted region, the steel must be heated within this temperature range and quenched to room temperature to form martensite. Martensitic stainless steels contain added carbon, which expands the gamma loop to allow higher chromium contents to be used. Because they can be heat treated, the martensitic stainless steels generally have higher strength than the austenitic and ferritic stainless steels. The martensitic stainless steels are listed below:

|       |                                                           |
|-------|-----------------------------------------------------------|
| 403   | Select quality for highly stressed parts                  |
| 410   | General-purpose martensitic stainless steel               |
| 414   | Ni added for improved corrosion                           |
| 416   | Higher P and S for improved machinability                 |
| 416Se | Se added for improved machined surfaces                   |
| 420   | Higher C for increased strength                           |
| 420F  | Free machining with higher P and S                        |
| 422   | Mo, V, and W added for increased strength and toughness   |
| 431   | Higher Cr, Ni added for improved corrosion resistance     |
| 440A  | Highest Cr, C added for increased hardness                |
| 440B  | Highest Cr, more C added for increased hardness/toughness |
| 440C  | Highest Cr, highest C for increased hardness/toughness    |
| 501   | Low Cr, Mo added                                          |
| 502   | Low C, Mo added                                           |

The compositional ranges for the martensitic stainless steels are shown in the aforementioned ASM table. Martensitic stainless steels are discussed in the next chapter.

*Precipitation Hardening Stainless Steels.* The precipitation hardening stainless steels are iron–chromium–nickel alloys that develop high strength and toughness through additions of Al, Ti, Nb, V, and/or N, which form precipitates during an aging heat treatment. The base microstructures of precipitation hardening stainless steels can be either martensitic or austenitic depending upon composition and processing. Some selected grades are listed below:

|     |                                                  |
|-----|--------------------------------------------------|
| 600 | Austenitic grade with Mo, Al, Ti, V, and B added |
| 630 | Martensitic grade with Cu and Nb added           |
| 631 | Austenitic grade with Al added                   |
| 633 | Austenitic grade with Mo and N added             |
| 635 | Martensitic grade with Al and Ti added           |

The compositional ranges of the precipitation hardening stainless steels are listed in the aforementioned ASM table.

*Other Stainless Steels.* There are many stainless steels that do not fall within the AISI classification system. These steels have proprietary compositions and trade names. Details of many of these steels can be found in the next chapter and in the Bibliography at the end of this chapter.

*Tool Steels.* Tool steels are alloy steels that are used to cut or machine other materials. Tool steels contain various levels of Cr, Ni, Mo, W, V, and Co. The categories of tool steels are:

|           |                                             |
|-----------|---------------------------------------------|
| M series  | Molybdenum high-speed steels                |
| T series  | Tungsten high-speed steels                  |
| Cr series | Chromium hot-work steels                    |
| H series  | Molybdenum hot-work steels                  |
| A series  | Air-hardening medium-alloy cold-work steels |
| D series  | High-carbon high-chromium cold-work steels  |
| O series  | Oil-hardening cold-work steels              |
| S series  | Shock-resistant steels                      |
| L series  | Low-alloy special-purpose tool steels       |
| P series  | Low-carbon mold steels                      |
| W series  | Water-hardening tool steels                 |

The compositional ranges of the various tool steels are listed in the table on pp. 758–759 of the *ASM Metals Handbook*, Vol. 20, 10th Edition, 1997. The high-speed steels are used in high-speed cutting tools such as drill bits. The hot-work tool steels are used in operations that utilize dies for punching, shearing, and forming materials at elevated temperatures, and the cold-work steels are used in similar operations at room temperature.

**Heat-Resistant Steels.** The upper temperature limit for use of carbon steels is about 370°C because of excessive oxidation and loss of strength. However, there are a number of alloy steels, called heat-resistant steels, that can be used at temperatures of 540–650°C. These steels include some of the ferritic stainless steels (405, 406, 409, 430, 434, and 439), quenched and tempered martensitic stainless steels (403, 410, 416, 422, and 431), precipitation hardening martensitic stainless steels (15-5 PH, 17-4 PH, and PH 13-8 Mo), precipitation hardening semiaustenitic stainless steels (AM-350, AM-355, 17-7 PH, and PH 15-7 Mo), and austenitic stainless steels (404, 309, 310, 316, 317, 321, 347, 202, and 216). In addition to the stainless steels, there are a number of proprietary alloys containing various levels of Cr, Ni, Mo, Nb, Ti, Cu, Al, Mn, V, N, or Si. The properties that are important to heat-resistant steels are creep and stress rupture. Creep is time-dependent strain occurring under stress. In more common terms creep is elongation or sagging of a part over time at elevated temperature. Stress rupture is a measure of the elevated temperature durability of material. These steels are generally specified under the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code.

**Wear-Resistant Steels (Austenitic Manganese Steels).** An important series of alloy steels are the austenitic manganese steels that contain 1.2% carbon and a minimum of 11% manganese. These steels, invented by Sir Robert Hadfield in 1882, are wear resistant and tough. Because they are difficult to hot work, these steels are usually cast into the final product form. The chemical compositional ranges for some selected austenitic manganese steels (ASTM A128) are listed below:

| Grade | C         | Mn       | Cr      | Mo      | Ni  | Si      |
|-------|-----------|----------|---------|---------|-----|---------|
| A     | 1.55–1.35 | 11 (min) | —       | —       | —   | 1 (max) |
| B1    | 0.9–1.05  | 11.5–14  | —       | —       | —   | 1 (max) |
| C     | 1.05–1.35 | 11.5–14  | 1.5–2.5 | —       | —   | 1 (max) |
| D     | 0.7–1.3   | 11.5–14  | —       | —       | 3–4 | 1 (max) |
| E1    | 0.7–1.3   | 11.5–14  | —       | 0.9–1.2 | —   | 1 (max) |

The carbon addition is necessary to maintain an austenitic microstructure at room temperature. All grades must be heat treated by solution annealing at 1010–1090°C for 1–2 h per inch of thickness followed by rapid water quenching. Because these alloys work harden during use, they are used in applications involving earthmoving (bucket blades), mining and quarrying (rock crushers), and railway trackwork (frogs, switches and crossings).

**Ultrahigh-Strength Steel**

**Maraging Steel.** Another important series of alloy steels are the maraging steels. They are considered ultrahigh-strength steels because they can be heat treated to yield strength levels as high as 2.5 GPa. They also have excellent ductility and toughness. There are basically four grades that are produced to strength levels between 1.4 and 2.5 GPa.

| <i>Grade</i> | <i>Ni</i> | <i>Co</i> | <i>Mo</i> | <i>Ti</i> | <i>Al</i> |
|--------------|-----------|-----------|-----------|-----------|-----------|
| 18Ni (200)   | 18        | 8.5       | 3.3       | 0.2       | 0.1       |
| 18Ni (250)   | 18        | 8.5       | 5.0       | 0.4       | 0.1       |
| 18Ni (300)   | 18        | 9.0       | 5.0       | 0.7       | 0.1       |
| 18Ni (350)   | 18        | 12.5      | 4.2       | 1.6       | 0.1       |

The numbers in parentheses represent the nominal yield strength level in ksi. All maraging steels must be heat treated to achieve the desired properties. The heat treatment cycle for the 18Ni (200), 18Ni (250), and 18Ni (300) grades requires a solution treatment at 820°C for 1 h per 25 mm of thickness, cooling to room temperature and an aging treatment at 480°C for 4 h. The 18Ni (350) grade has an extended aging time of 12 h. The heat treatment develops a martensitic microstructure on cooling from austenite at 820°C. The aging step precipitates intermetallic compounds, e.g.,  $\text{Ni}_3\text{Mo}$  that strengthen the martensitic matrix. Maraging steels can be machined before the aging treatment and have good weldability and excellent fracture toughness. They have found applications in missile and aircraft parts that require exceptional performance.

**Music Wire.** One of the strongest steel products commercially available is music wire. These wires can achieve levels of tensile strength approaching 5 GPa. The steel is basically SAE/AISI 1080. To obtain the ultrahigh-strength levels, rods of SAE/AISI 1080 are isothermally transformed to fine pearlite in a process known as patenting. The rods are then cold drawn to wire using large reductions in wire diameter through each die. The cold reduction forces the ferrite and cementite in the microstructure to align in a preferred orientation or fiber texture. The wires are used in musical instruments where they can be stretched under high tension to achieve certain musical notes. Ultrahigh-strength wires are also used to strengthen the rubber in automobile tires.

## 7 SUMMARY

Steel is one of the most versatile materials in today's society. It can be produced with a wide range of properties and is used in millions of applications. For example, stainless steels are used for their corrosion resistance, interstitial-free steels are used for their excellent formability characteristics, iron–silicon alloys are used for their electrical properties, austenitic manganese steels are used for their wear and abrasion resistance, microalloyed steels are used for their high strength, patented and cold-drawn eutectoid steel wires are used for their ultrahigh strength, dual-phase and trip steels are used for their energy absorption capability in a vehicle collision, and tool steels are used for their outstanding ability to cut and machine other materials. No other material can span such a range of properties and characteristics.

Stainless steels are those alloys of iron and chromium, with or without other elements, containing at least 11% chromium. This is the minimum amount of chromium necessary to form a stable, passive chromium oxide film. It is this film that is the basis for the corrosion resistance of all stainless, and most nickel base, corrosion-resistant alloys.

There are six basic classifications of stainless steels: ferritic, martensitic, martensitic age hardening, duplex austenitic–ferritic, and austenitic. The most commonly produced of these are the ferritics 409, for automotive applications, and 430 for corrosion-resistant/decorative uses, the martensitic grade 410, and the age-hardening martensitic 17-4PH®. Of the austenitic–ferritic duplex grades, alloy 2205 is the most broadly available. The two most used austenitic stainless grades are 304L, and 316L. A number of “superaustenitics” use nitrogen to maintain an austenitic structure with relatively high molybdenum, some 6%, and moderate nickel, 18–25%. Of the higher nickel grades 20Cb-3® stainless is used for sulfuric acid and general chemical processing. The most commonly used of the very high nickel alloys is C-276. The austenitic stainlesses form a continuum with the nickel base heat- and corrosion-resistant alloys. They are distinguished on the basis of nickel content by arbitrary or commercial definitions. There is no recognized metallurgical definition of where stainless ends and nickel-base begins.

1 EFFECT OF ALLOYING ELEMENTS

The corrosion behavior of the alloying elements in pure form influences the corrosion properties of the alloys.

Chromium is the first example, with outstanding corrosion resistance in the passive state. In solutions of neutral pH, dissolved oxygen from the air is sufficient to maintain passivity. But in low-pH solutions, stronger oxidizing agents must be present, and halogen or sulfuric acids absent, in order to stabilize the passive condition. Chromium metal is not resistant to corrosion by reducing acids.<sup>1</sup>

Some examples, from Uhlig,<sup>1</sup> of corrosion resistance of electrodeposited chromium:

| Acid or Salt    | Concentration (%) | Temperature |     | Corrosion Rate    |                     |
|-----------------|-------------------|-------------|-----|-------------------|---------------------|
|                 |                   | °C          | °F  | (mm/yr)           | (mils/yr)           |
| Acetic          | 10                | 58          | 136 | 0.38              | 15                  |
| Ferric chloride | 10                | 58          | 136 | 0.41 <sup>a</sup> | 16 <sup>a</sup>     |
| Formic          | 10                | 58          | 136 | 30                | 1200                |
| Hydrobromic     | 10                | 58          | 136 | 4.7               | 186                 |
| Hydrofluoric    | 10                | 12          | 54  | 2.5               | 1000                |
| Phosphoric      | 10                | 58          | 136 | 0.86              | 34                  |
| Sulfuric        | 10                | 12          | 54  | 0.28              | 11                  |
| Sulfuric        | 10                | 58          | 136 | 250               | 10,000 <sup>a</sup> |
| Sulfuric        | 100               | 12          | 34  | 0.76              | 30                  |
| Sulfuric        | 100               | 58          | 136 | 1.8               | 69                  |

<sup>a</sup>Pitting occurred, this number does not reflect uniform corrosion.

Three points can be made from this data. First, chromium as an alloying element is not particularly effective in promoting resistance to reducing or halogen acids. Second, in solutions of some halogen salts the passive layer was maintained by oxygen dissolved in the solution. Third, sulfuric acid behaves as a reducing acid in lower concentrations but as an oxidizing acid in concentrated form. When selecting alloys to resist sulfuric acid, one must bear this in mind.

Stainless steels containing only chromium and iron, specifically the ferritic and martensitic stainlesses, likewise have poor resistance to sulfuric acid solutions but may resist nitric acid. These chromium–iron alloys are not resistant to corrosion by halogen acids or by chloride salts. Those ferritic alloys that do have good to excellent chloride pitting resistance, such as E-BRITE® and AL29-4C®, gain that resistance by the addition of 1 and 4% Mo, respectively.

Austenitic nickel alloys with resistance to concentrated (oxidizing) sulfuric acid require high chromium, such as the Krupp VDM alloy 33, or silicon as in Haynes® Mickel alloy D-205, and the stainless grades A610, A611, and Sandvik® SX.

There are a few highly corrosion resistant nickel alloys with little or no chromium, including the various Ni–Mo “B” grades and the 67Ni–31Cu alloy 400. Excellent in reducing environments, they have almost no tolerance to oxidizing compounds in the environment. A newly developed nickel–molybdenum alloy,

B-10, includes 8% Cr in its composition for limited resistance to low levels of oxidizers.

Molybdenum, in contrast to chromium, has very low resistance to oxidizing solutions but does resist reducing and halogen acids. Oxidizing acids such as nitric, aqua regia, and concentrated sulfuric acids readily dissolve molybdenum metal. Hydrofluoric acid does not affect Mo, and hot (110°C) hydrochloric acid attacks molybdenum metal only slowly.<sup>1</sup> In both stainless steels and nickel-base alloys, molybdenum as an alloying element is required for resistance to halogen acids and to pitting by acid or oxidizing chlorides. The amount used ranges from 2% in 316 L stainless up to 24–30% in alloys B through B-10. As an alloying addition, molybdenum improves the stability of the passive layer in the presence of halogens.

Tungsten at the 2–4% level is used, along with molybdenum, to improve chloride pitting corrosion resistance.

Nickel metal in general is attacked by oxidizing solutions, while reducing solutions are less aggressive. Some examples<sup>1</sup> follow:

| Acid         | Notes                    | Concentration (%) | Temperature |     | Corrosion Rate |           |
|--------------|--------------------------|-------------------|-------------|-----|----------------|-----------|
|              |                          |                   | °C          | °F  | (mm/yr)        | (mils/yr) |
| Hydrochloric | Air saturated            | 10                | 30          | 86  | 2              | 80        |
| Hydrochloric | N <sub>2</sub> saturated | 10                | 30          | 86  | 0.25           | 10        |
| Sulfuric     | Aeration by convection   | 10                | 77          | 170 | 0.31           | 12.1      |
| Sulfuric     | Air saturated            | 10                | 82          | 180 | 4              | 160       |

Nickel metal is strongly attacked by phosphoric acid solutions containing ferric (oxidizing) salts, whereas it resists phosphoric acid solutions that are free of oxidizing compounds. Nickel metal resists neutral chloride solutions, such as sodium chloride, but is attacked by acid or oxidizing chloride salts. Alloys for use in reducing acids invariably have a considerable nickel content, ranging from as little as 8% in 304L to as much as 71% in alloy B-2.

Copper is generally resistant to reducing acid solutions containing only low levels of oxygen but is readily attacked by oxidizing acids. These include nitric, sulfurous, and concentrated sulfuric acids, as well as solutions containing oxidizing salts, such as ferric chloride. Copper in solution tends to reduce the corrosion rate of stainless alloys in (reducing) sulfuric acid. Those alloys intended for use in environments containing much sulfuric acid invariably have some copper as an alloy addition. These include 904L, 20Cb-3, 825, Nicrofer® 3127 hMo (alloy 31), and the Hastelloy® alloys G, G-3, and G-30.

Additions of some 4 or 5% silicon increase corrosion resistance to oxidizing environments. The silicon is primarily used in alloys meant to withstand concentrated, hence oxidizing, sulfuric acid. Such alloys in current production include A610, A611, Sandvik SX, and Haynes D-205. The use of silicon as an alloying element for corrosion resistance dates back to before Word War I. Although not a stainless, one of the oldest and most generally corrosion-resistant alloys ever developed is the 14.5% silicon cast iron, Duriron. A silicon oxide film is believed responsible for this grade’s useful resistance to environments

ranging from oxidizing to reducing. This includes seawater, organic and many inorganic acids, though not halogen acids. Lack of strength and ductility limit the cast iron's range of use.

When one speaks about the effect of this or that pure chemical on an alloy, one must emphasize that real industrial environments are complex mixtures of chemicals. These mixtures may behave in surprising ways; quite unlike what one might expect from the behavior of alloys in pure, laboratory-controlled environments. Corrosion rates depend not only upon the concentrations of various chemicals but also on the temperature. The temperature of liquid inside a vessel is one point that can be measured, but the temperature at the surface of submerged heating coils in that vessel is another, and higher value. Likewise the concentration of, say an acid, in the vessel is not the same as the concentration at the point where that acid is introduced to the mixture.

The most commonly used corrosion-resistant alloys are the stainless steels 304 (18% Cr 8% Ni, commonly known as 18–8 stainless) and 316 (17% chromium 11% nickel 2% molybdenum). The more corrosion-resistant nickel alloys, such as C-276, have much higher levels of nickel, 57%, and molybdenum, 15.5%. Commercially pure nickel, and nickel–copper alloys are used for special environments.

Oxidizing and reducing environments are defined chemically with respect to whether hydrogen is oxidized or reduced under the environment in question. In an oxidizing environment, hydrogen will only be present chemically combined with some other element, for example, with oxygen to form  $H_2O$ . In a reducing environment, that  $H^+$  will be reduced to hydrogen gas,  $H_2$ .

Common oxidizing chemicals are nitric acid,  $HNO_3$ , and certain salts such as ferric chloride,  $FeCl_3$ , and cupric chloride,  $CuCl_2$ . The ferric and cupric ions are at a relatively high valences, +3 and +2, respectively, and readily accept electrons, or oxidize, other materials, to get their own valences reduced to a more stable level. Sulfuric acid,  $H_2SO_4$ , is normally a reducing acid. At high concentrations, above about 95%, sulfuric acid changes its character and becomes an oxidizing acid. Of course, dissolved oxygen contributes to the oxidizing character of an environment. To some extent so does dissolved elemental sulfur.

To resist oxidizing conditions an alloy must contain some amount of chromium. For oxidizing acid service simple materials such as 304 (18% Cr 8% Ni) or 316 (17% Cr 11% Ni) are often used. An unusually high level of chromium, 33%, is present in a newly developed alloy, UNS R20033, meant to resist very oxidizing acids. In any of these alloys the nickel content is necessary to make a stable austenitic alloy, but it does not contribute specifically to oxidizing acid resistance. Small additions of molybdenum or copper may be tolerated in these alloys to enhance resistance to chlorides or sulfuric acid. But neither Mo nor Cu themselves are helpful in resisting strongly oxidizing chemicals.

A common, and severe, test for resistance to oxidizing acids is boiling 65% nitric acid. The test is run for five periods of 48 h each, specimens being weighed after each test period, and the results averaged. This test is a good measure of resistance to intergranular corrosion in a sensitized alloy, as well as to general corrosion in nitric acid. Test results<sup>2</sup> show 2205 0.13–0.20 mm/yr, which is good, 304 0.23 mm/yr, and RA333®, which has been stabilize annealed 1700°F, at 0.29 mm/yr. In the case of RA333 it is the high chromium that helps, in spite

of 3% Mo. Other molybdenum bearing grades do not fare so well, 316L (2% Mo) at 0.87 mm/yr after only 24 h, AL-6XN® (6.3% Mo) at 0.74 mm/yr, 625 (9% Mo) at 0.76 mm/yr, and C-276 (15.5% Mo) at 0.74 mm/yr. These results do not mean that one cannot successfully use a higher Mo alloy in the presence of any nitric acid at all. They do indicate that high-molybdenum alloys may not behave at all well in hot, concentrated oxidizing industrial environments.

One cannot readily find boiling 65% nitric acid (ASTM A262C) data for the 66% Ni–31% Ni alloy 400 (Monel® 400) or for the assorted B alloys—B, B-2, B-3, or B-4. Their corrosion rates in nitric acid are simply too high for the test to have any practical value. Alloys 400, B, and B-2 have no deliberate chromium addition, B-3 and B-4 only about 1.3% Cr. These grades have excellent resistance to various reducing environments, but because there is essentially no chromium present, they will literally dissolve in nitric acid. Likewise, they are attacked by ferric, cupric, and chlorate ions, and even dissolved oxygen in HCl.

The common “reducing” acids are sulfuric under about 95%, phosphoric ( $\text{H}_3\text{PO}_4$ ), and hydrochloric. Of these by far the most corrosive is HCl, phosphoric being the less troublesome. Because reducing industrial environments often do contain some oxidizing salts or oxygen from the air, most alloys used to withstand reducing chemical environments will contain chromium, at least 15%. The alloy additions used to resist the reducing components of the environment are nickel (Ni), molybdenum (Mo), and copper (Cu).

In sulfuric acid some amount of copper is usually used, such as in 20Cb-3 stainless, 904L, or 825. Even copper salts in the acid will reduce corrosion attack of stainless. 20Cb-3 uses carefully balanced proportions of Cu and Mo to resist sulfuric acid corrosion.

## 2 SOME FORMS OF CORROSION

### 2.1 General Corrosion

This is the most common form of corrosion, accounting for the greatest tonnage loss of metal. It is characterized by relatively uniform attack of the entire area exposed to the corrosive environment. The passive film slowly dissolves but continually reforms. Since the attack is linear with time, the life of equipment subject to general corrosion is reasonably predictable. If the passive film is locally disrupted, as by chlorides, corrosion modes such as pitting, crevice, and stress corrosion may occur. These are more difficult to predict and tend to cause premature equipment failures. Erosion may also remove the passive film and contribute to much higher than expected general corrosion rates.

Stainless steel passivates simply by being exposed to air. A metallographic specimen of AL-6XN, for example, must be etched immediately after polishing. Otherwise it will passivate in air so that a uniform etch cannot be achieved. Passivation in acid is not required. But, during normal fabrication practice, enough iron is picked up to cause surface rusting in damp weather. A treatment in nitric–hydrofluoric acid may be used to remove this surface iron contamination.

Uniform corrosion rates may be stated as an average metal thickness loss with time, mils per year, or millimeter per year. A convenient rating for metals subject to uniform attack based on corrosion rates follows:

Excellent—rate less than 5 mils/yr (0.13 mm/yr). Metals suitable for making critical parts.

Satisfactory—rate 5 to 50 mils/yr (0.13–1.3 mm/yr). Metals generally suitable for noncritical parts where a higher rate of attack can be tolerated

Unsatisfactory—rates over 50 mils/yr (1.3 mm/yr). Metals usually not acceptable in the environment.

An approximate ranking of a few common alloys by increasing resistance to general corrosion would be 304L, 316L, 20Cb-3/825, AL-6XN, 625, and C-276. Alloy selection does depend upon the exact corrosive environment in question. Some specific examples include hot concentrated caustic, where commercially pure nickel or the 76% nickel alloy 600 are used. For sulfuric acid alloys 20Cb-3 or 825 are usually chosen—however, if chlorides are present in the acid, one of the 6% molybdenum grades such as AL-6XN would be preferred. AL-6XN is used for organic acids, such as naphthenic acid in refinery service. For nitric acid service chromium is beneficial, molybdenum not. Alloys commonly selected include 304L or a low carbon version of 310. RA333 is used when the same piece of equipment must see very high temperatures, in the red heat range, in one zone and aqueous corrosion in another.

## 2.2 Stress–Corrosion Cracking

For just about every alloy there is some chemical environment that, combined with stress, will cause cracking. For brass that environment is ammonia or other nitrogen compounds. The source of stress is usually residual forming and welding stresses, which may reach the yield point of the material. Operating stress is rarely the issue.

For austenitic stainless steels chlorides are the major cause of stress–corrosion cracking (SCC). An example is hot potable water under heat-transfer conditions, which permit chlorides to concentrate locally. Susceptible alloys include 304L, 316L, 321, and 347. Some 95% of 316L chemical plant equipment failures may be attributed to chloride stress–corrosion cracking. The chlorides concentrate from trace amounts present in steam for heating, or the cooling water in heat exchangers, as well as from the product.

Chloride SCC occurs most quickly in stainless steels with about 8–10% nickel, alloys with much lower, or much higher, nickel content being less susceptible. As thermal stress relief is rarely practical with stainless fabrications, the metallurgical solution is a change in alloy. Nickel-free ferritic steels, such as E-BRITE are highly resistant to chloride SCC but impractical to fabricate into a vessel.

The traditional solution in the United States has been to go to a higher nickel alloy. Alloys with about 30% or more nickel are generally considered to be good engineering solutions to most chloride SCC problems, although they will crack under very severe conditions. 20Cb-3 at about 34% and 825 at 40% nickel have long been chosen for this service. Likewise the fine-grained Incoloy® 800, UNS

N08800, 31%Ni, had been used in years past. However, this low-carbon, fine-grained version of 800 is now rarely available. Regardless of what it is called, “800” today usually is 800HT, UNS N08811, a higher carbon, coarse-grained version. This grade is designed to maximize creep rupture strength for high-temperature applications.

Since the mid-1980s the 6% molybdenum superaustenitics have become available. Grades such as 254 SMO® with only 18% nickel, or AL-6XN at 24% nickel, have been used effectively to resist chloride SCC. The material cost of the “6-moly” grades is approximately three times that of 316L stainless. Although lower in nickel, molybdenum contents above 2% tend to decrease susceptibility of austenitic stainless to chloride SCC.<sup>3</sup>

For greater resistance to both corrosion and chloride SCC the most used grade has been C-276, at 57% Ni 15.5% Mo. There are now a number of alloys in this class, including ALLCORR™, C-22, Inconel® 686, C-2000, 59, and a new Japanese grade, MAT 21. These very high nickel alloys can easily reach five times or more the cost of 316L stainless. They are metallurgically excellent solutions to chloride SCC, particularly in severe environments. However, they are expensive choices for service conditions under which 316L lasted a few years before cracking. There is a less expensive choice, one which has long been used in Europe. That is a duplex stainless steel, which is about half austenite and half ferrite. Duplex stainless steel is a practical solution to most 304L or 316L SCC failures. The most commonly available duplex in North America is 2205, at a cost roughly 20% above that of 316L.

Other forms of stress–corrosion cracking in stainless steels include caustic cracking and polythionic acid stress–corrosion cracking. Caustic may crack carbon steel as well as stainless. High nickel alloys, such as alloy 600 or, better, commercially pure nickel (UNS N02201) are used.

Polythionic acid stress–corrosion cracking (PASSC) is caused by sulfur compounds in the environment and most often encountered in refineries. Any stainless or nickel alloy that has been sensitized can be subject to PASCC. High nickel does not help, even 600 alloy will crack when sensitized.<sup>4</sup> To resist this form of SCC the alloy must contain a strong carbide-forming element, or “stabilizing” element, such as columbium or titanium. Examples include 321, 347, 20Cb-3, 825, and 625. In addition the alloy must be given a stabilizing anneal so that the carbon is effectively combined with the Cb or Ti. RA333, because of its tungsten and molybdenum content, resists PASCC when stabilize annealed about an hour at 1700°F (927°C).

Normally, 304H or 316H would be quite sensitive to polythionic acid stress cracking, as these higher carbon, solution-annealed alloys readily sensitize. The matter has been addressed at one refinery by fabricating the equipment from one of these H-grade stainless steels, then stabilize annealing the completed fabrication. A temperature of about 1650°F (900°C) for a minimum of 1 h is used. This does precipitate carbides at the grain boundaries, but temperature is high enough to permit chromium to diffuse back into the Cr-depleted grain boundary zone. In addition, this treatment relieves over half of the residual fabricating stress, thus reducing susceptibility to chloride stress–corrosion cracking as well.

## 2.3 Pitting Corrosion

Pitting is an extremely localized form of corrosion that results in holes in the metal. Although total metal loss may be small, the equipment may be rendered useless because of perforation. Pitting usually requires a long initiation period before attack is visible. Once a pit has begun, the attack continues at an accelerating rate. Pits tend to grow in a manner that undermines or undercuts the surface. Typically a very small hole is seen on the surface. Poking at this hole with a sharp instrument may reveal a rather cavernous hole under what had looked like solid metal. In effect, a pit may be considered a self-formed crevice. Pitting attack increases with temperature.

Chloride solutions are the most common cause of pitting attack on stainless steels and nickel alloys. The alloying additions of molybdenum, nitrogen, and, to some extent, chromium, all contribute to pitting resistance. A laboratory measure of resistance to pitting corrosion is the critical pitting temperature, or CPT, which is the highest temperature at which an alloy resists pitting in a given environment. Alloy ranking with respect to chloride pitting resistance would be 304L (0% Mo, poor), followed by 316L (2% Mo), then four austenitics each with about 3% molybdenum, 20Cb-3/825/317L/RA333, the duplex 2205 (3% Mo 0.16% N), AL-6XN (6.3% Mo 0.22% N), 625 (9% Mo), and C-276 (15.5% Mo). Alloys AL-6XN and higher have chloride sufficient resistance to be used in hot seawater service. The lower molybdenum grades, including 2205 with 3% Mo, are unsuitable for use in seawater.

## 2.4 Crevice Corrosion

Crevice corrosion, more so than pitting, is the limiting condition that often prevents the use of conventional austenitic stainless in chloride environments. The attack usually occurs in small volumes of stagnant solution under gasket surfaces, lap joints, marine fouling, solid deposits, and in the crevices under bolt heads and the mating surfaces of male and female threads. The mechanism involves oxygen depletion in the crevice, followed by chloride ion concentration and increase in acidity (decrease in pH) within the crevice. In a neutral, pH 7, chloride solution service, the liquid within a crevice may contain 3–10 times as much chloride as the bulk solution, and have a pH of only 2–3. Susceptibility to crevice corrosion increases rapidly with temperature. Molybdenum and nitrogen additions to nickel–chromium–iron alloys improve their resistance to crevice corrosion. Together with the use of appropriate materials, design practice to minimize crevices and maintenance procedures to keep surfaces clean are required to combat the problem.

The usual laboratory measure of resistance to crevice corrosion is the critical crevice corrosion temperature, or CCCT, which is the highest temperature at which an alloy resists crevice corrosion in a given environment. For a given environment the CCCT is usually significantly lower than the CPT. Crevice corrosion resistance as measured by the ferric chloride test relates, to a degree, to performance in seawater. Here are the results for a number of alloys<sup>2</sup>—temperature for initiation of crevice corrosion in ferric chloride ( $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ ), 10%  $\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$ , per ASTM G48 Practice B, (PRE)  $N = \text{Cr} + 3.3\% \text{ Mo} + 30\% \text{ N}$ :

| Alloy    | Mo<br>(%) | Temperature |     | Pitting Resistance<br>Equivalent (PRE),<br>N | Ref. |
|----------|-----------|-------------|-----|----------------------------------------------|------|
|          |           | °C          | °F  |                                              |      |
| 316L     | 2.1       | −3          | 27  | 23                                           | 5    |
| 825      | 2.7       | −3          | 27  | 30                                           | 5    |
| 317L     | 3.2       | 2           | 35  | 29                                           | 5    |
| 2205     | 3.1       | 20          | 68  | 38                                           | 5    |
| 317LMN   | 4.4       | 20          | 68  | 34                                           | 5    |
| 28       | 3.5       | 24          | 75  | 38                                           | 6    |
| 904L     | 4.4       | 24          | 75  | 35                                           | 5    |
| 904L     | 4.4       | 25          | 77  | 35                                           | 7    |
| G        | 6.5       | 30          | 86  | 43                                           | 5    |
| 28       | 3.5       | 35          | 95  | 39                                           | 7    |
| 2507     | 4.0       | 35          | 95  | 47                                           | 7    |
| 1925hMo® | 6.2       | 40          | 104 | 47                                           | 7    |
| 33       | 1.4       | 40          | 104 | 50                                           | 7    |
| AL-6XN   | 6.2       | 43          | 110 | 48                                           | 5    |
| 625      | 9.0       | 45          | 113 | 51                                           | 5    |
| 625      | 9.0       | 55          | 131 | 51                                           | 6    |
| 31       | 6.5       | 55          | 131 | 54                                           | 6    |
| G-30®    | 5.5       | 50          | 122 | 48                                           | 7    |
| C-276    | 15.4      | 55          | 130 | 66                                           | 5    |

## 2.5 Intergranular Corrosion

Intergranular corrosion consists of localized attack along the grain boundaries of the metal. Sensitization to this attack in stainless or nickel alloys is caused by precipitation of chromium-rich carbides in the grain boundaries, at a temperature low enough that a chromium-depleted zone forms. This precipitation most commonly occurs from the heat of welding. It may also result from a slow cool after annealing, or from prolonged exposure to intermediate temperatures, roughly 850–1470°F (450–800°C), in service. For exposures at very long times, or around the high end of this range, diffusion of chromium back into the depleted zone will restore the corrosion resistance.

A most effective means of combating intergranular corrosion is to restrict the carbon content of the alloy. In the stainless “L” grades 0.03% maximum is considered sufficient. High chromium and molybdenum additions, as in AL-6XN, also reduce the chance of intergranular attack. Another approach is to add columbium or titanium to tie up the carbon, the same as is done to resist polythionic acid stress–corrosion cracking. 20Cb-3 stainless takes both approaches, being melted to low carbon, as well as having a columbium addition.

## 2.6 Galvanic Corrosion

An electrical potential, or voltage, difference will exist between two different metals that are in electrical contact and immersed in a corrosive solution. This potential difference causes current to flow and the less noble, or more anodic, metal suffers increased corrosion rate. The severity of attack depends upon the relative voltage difference between the metals, the relative exposed areas of each, and the particular corrosive environment.

The most common example is the old-fashioned flashlight battery, or dry cell. It has a shell of zinc metal (less noble, or anodic), filled with a moist, corrosive

chloride paste that conducts electricity. The center post is made of graphite, which is quite noble (cathodic, does not tend to corrode). The potential (voltage) difference between zinc and graphite happens to be about 1.5 V. When an electric connection is made in a flashlight, the zinc corrodes, giving up electrons, which flow through the lightbulb toward the graphite cathode, the positive pole. In this case, because generating electricity is the point, no one minds that the zinc corrodes and gets used up.

The ratio of cathodic (noble) to anodic areas is an important factor in galvanic corrosion. An undesirable situation is a large cathode connected to a small anode, or less noble metal. This can develop high current density, hence severe corrosion, at the anode. In that common zinc dry cell the zinc anode has a much larger area than the graphite cathode, so it has some useful working life before corroding through the zinc case.

For example, a large area of stainless in contact with a small surface area of carbon steel is undesirable. The potential difference will tend to corrode the carbon steel, and the very large area of stainless will make that corrosion occur quickly. The reverse condition is preferred. That is, a small area of stainless (or more noble metal) may be coupled with a much larger area of carbon steel (anodic) without significant problems. "Significant" depends upon the application. In the past, when ferritic stainless trim was used on carbon steel automobile bodies, the steel would tend to corrode most severely underneath the trim. In part that was because the crevice trapped salt, but it was accentuated by the galvanic difference between ferritic stainless and carbon steel.

There is some potential difference among the various stainless and nickel alloys. In practice, galvanic corrosion is rarely a problem among these various alloys. There is, however, a significant potential difference between copper alloys and stainless. So long as the stainless is passive (not actively corroding) it is enough more noble than copper to corrode the copper alloy. An example is when a heat exchanger with a Muntz metal (60% Cu, 40% Zn) tubesheet is retubed with AL-6XN alloy instead of the original copper alloy tubes. The potential difference is enough to corrode the copper alloy tubesheet. One ought either to replace the tubesheet as well, with stainless, or retube using a copper base alloy.

Graphite is at the noble end of the galvanic series. If graphite is in contact with stainless or nickel alloys in a corrosive environment, those alloys may corrode preferentially.

Galvanic effects have a positive side and may be used to protect equipment from corrosion, a common example being a zinc coating on steel. The zinc corrodes preferentially, and in doing so protects the steel from corrosion (rusting). Zinc or magnesium anodes are often connected to equipment from chemical process to steel ship hulls to protect them from corrosion.

### **3 AOD, DUAL CERTIFICATION, AND CHEMISTRY CONTROL**

Most stainless steels, and a few higher nickel alloys, are available with different levels of carbon. For resistance to intergranular corrosion, a low carbon is preferred, usually 0.03% carbon maximum in stainless. Such a stainless is referred to as an "L" grade, e.g., 304L and 316L. With respect to aqueous corrosion resistance, the lower the carbon, the better. For high-temperature service the opposite is true, and some minimum amount of carbon is required for both tensile and creep rupture strength.

The argon–oxygen decarburization (AOD) process for refining stainless steel was introduced in the 1970s. This made profound changes in how existing grades were produced, as well as permitting totally new grades to be developed. Three of these changes are worth discussing—carbon, sulfur, and precise control of chemistry.

Prior to the AOD, carbon could not be removed in the refining process without also removing chromium. Low-carbon grades could only be produced by starting with low-carbon raw materials, specifically low-carbon ferrochrome. The expense of low-carbon ferrochrome meant that the L grades were inherently more expensive. The AOD now permits refining carbon to very low levels, even with starting stock of higher carbon.

Industrywide specifications such as the American Society for Testing and Materials (ASTM) were written prior to the introduction of this new melting process. For example, ASTM A 240 for 304 stainless, UNS S30400, calls out 0.08% carbon maximum, no minimum, 30,000 psi minimum yield strength. Low carbon 18–8, 304L, S30403 is limited to 0.03% carbon, with a consequent lower limit for yield strength, 25,000 psi minimum. In addition, there is a 304H, meant for high-temperature use, with carbon specified as a range, 0.04–0.10%, and annealing and grain size requirements. This constitutes three separate grades. It is more economical if the mills can melt steel to only two, not three, different levels of carbon, and dual certify. Consider 304, UNS S30400. As the carbon is specified only as a maximum, it might be possible to melt 304 to 0.03 max carbon. Lower carbon would also result in lower than the 30,000 psi yield strength required. However, using the AOD it is now possible to add a very small, precisely controlled amount of nitrogen. This does not harm intergranular corrosion resistance but it does tend to increase room temperature tensile properties. With care in annealing practice, it is possible to produce 304 with low enough carbon to meet the 304L specification, yet with high enough yield strength to meet 304 requirements. As this metal meets all specified requirements of both 304L and 304, the mill test report will show both S30403 and S30400, i.e., dual certified.

S30403/S30400 is appropriate for corrosion service but not for high-temperature mechanical properties. For useful creep rupture strength some minimum amount of carbon is required, typically 0.04%. The situation was addressed a few years ago by adding a number of H grades to ASTM A240, with controlled carbon for high-temperature strength. The stainless 304H, S30409, has carbon specified 0.04–0.10% for high-temperature strength. In addition, there are grain size and minimum anneal temperature requirements. The 304, S30400, has no requirement for minimum carbon, control of grain size, or annealing temperature. Therefore any 304H containing no more than 0.08% carbon will meet 304 requirements, and may be dual-certified with 304. One should note that dual certified 304L/304 is suited only for aqueous corrosion service but would have rather low strength at high temperature. Likewise dual-certified 304/304H is meant for high-temperature service but may be unsatisfactory for welded construction in a wet corrosive environment. In practice, there is rather little actual S30400 produced as sheet or plate at this time. Most is dual certified, one way or another.

Like carbon, sulfur can now readily be refined to very low levels, typically less than 0.005%. Compare this with typical ASTM A 240 levels of 0.030% S

maximum. Usually, stainless intended for plate is refined to a low-sulfur level to improve hot workability. Plate is generally formed and welded, with rather little machining by the customer. Low sulfur is quite detrimental to machinability. As bar products are commonly meant to be machined, most stainless bar actually must be resulfurized to some level, about 0.02%, for improved machinability. When this plate is intended to be drilled for a tubesheet, machineability becomes important and a resulfurized grade, still within the old 0.030 sulfur maximum, may be chosen.

It is precise control of chemistry, in particular nitrogen, that has permitted development of the superaustenitic 6% molybdenum grades. The ability to closely control nitrogen as an alloying addition has also tremendously improved the weldability of duplex stainless. Whereas formerly the only duplex stainless used in North America was 3RE60, and that only in tubing, today several grades of duplex stainless plate, pipe, and bar products are used in significant and growing amounts.

Chemistry control also means that the producer will minimize the use of expensive alloying elements. To remain competitive, mills now melt to the bottom end of the allowable range. One consequence for the user is that 316L stainless, specified as 2.00–3.00% molybdenum, now has a melt range of about 2.00–2.10% Mo. Through the 1970s the typical Mo level of 316L was about 2.3%. In addition, the average nickel content has dropped from just below 12% in the 1970s, down to around 10.2% Ni as currently produced. The result has occasionally been that 25-yr-old 316L equipment, replaced in kind, gave unexpectedly short life. In part, of course, this is due to increased corrosive conditions from recycling, rather than dumping, waste.

#### **4 AVAILABILITY**

The metallurgical aspects of alloy selection are well covered in this and other works. Along with corrosion resistance, strength, and fabricability, one of the most important material properties is availability. On a large project most alloys can be made in all product forms, in full mill heat lots. A contemporary example is 317LMX®, used as flat-rolled product, in mill heat lot quantities, for flue gas desulfurization scrubbers. This grade is rarely, if ever, carried in stock by mills or service centers.

Few mills produce all the forms, such as sheet, plate, bar, pipe, pipe fittings, and appropriate weld fillers, needed to fabricate a chemical process vessel. The minimum quantity a mill requires per product form is large, and lead times can be significant. This may limit flexibility in the event of error, last minute design changes, or later maintenance needs.

Consider what alternate, if more expensive, grade may be used to fill in for unavailable product forms or sizes. For example, AL-6XN has occasionally been used to fill out a bill of materials specified 317LMX®. The stainless grades 304L and 316L are used in such quantity that availability is unlikely to be an issue. The same may not be true for more highly alloyed or specialized materials.

#### **5 FERRITIC STAINLESS STEEL**

The ferritic grades listed below exhibit corrosion resistance over a very wide range. All are subject to severe embrittlement after prolonged exposure in the

700–1100°F (370–600°C) temperature range. Alloy 409 is weldable and is the alloy used for automotive exhaust systems and catalytic converter shells. It has some useful high-temperature oxidation resistance to about 1200°F (650°C). In plate gauges it may be welded with ERNiCr-3 for better toughness. Alloy 409 is not suited for decorative applications as it may rust from exposure to weather. Alloy 416 is free machining, available both as a ferritic and a martensitic version; 430 is commonly used for decorative purposes as well as food-handling equipment. E-BRITE has chloride pitting resistance equal or superior to 316L stainless, and practical immunity to chloride SCC. E-BRITE is currently available only as tubing for heat exchangers. AL29-4C is extremely resistant to chloride pitting and used for heat exchanger applications, available only as tubing or thin strip.

6 MARTENSITIC STAINLESS STEELS

The only one of these that is readily welded is 410S. The higher carbon 410 may require significant preheat and postweld anneal. Consider the nickel alloy filler ERNiCr-3 for maximum resistance to weldment cracking, at a sacrifice in strength and hardness. The corrosion resistance of 410 depends upon the heat-treated condition. For maximum corrosion resistance temper either below 750°F (400°C) or above 1100°F (600°C). Both 410 and the martensitic 416 are used in sporting arms construction. The 440 series are used for cutting tools, 440A and B for pocket knives; 440C has the best edge retention and is used for fine custom knives and surgical tools.

7 AGE-HARDENING MARTENSITIC STAINLESS STEELS

These grades combine useful corrosion resistance with simple heat treatment. The most widely used is 17-4PH. They are susceptible to chloride stress–corrosion cracking. Susceptibility depends somewhat upon grade and aging temperature.

Age-Hardening Alloys (%)

8 DUPLEX STAINLESS STEELS

Duplex stainless steels are characterized by high strength and good resistance to chloride stress–corrosion cracking. They represent a more economical solution to the problem of stainless SCC than the use of a high-nickel alloy. The lower grades, such as 2304, may be used to replace carbon steel in large part because the higher strength permits such weight reduction. The two grades most available from North American service centers, in a range of product forms, are 2205 and 2507. Alloys Zeron® 100, 2507, and 255 have sufficient chloride pitting resistance for seawater service.

9 AUSTENITIC STAINLESS AND NICKEL ALLOYS

These nickel bearing alloys are used for the majority of corrosive environments. Alloy 316L is by far the most common choice for chemical process equipment. Formerly, when 316L was inadequate, the designer switched to the high end of the spectrum, alloy C-276, which is still considered the most broadly useful of the high alloys. Today there are numerous other choices, ranging from those of intermediate cost to alloys superior to C-276 in specific environments.

Types S30600, S32615, and alloy D-205™ are specialized high-silicon materials intended for concentrated sulfuric acid heat exchanger service. Weldability is limited. A very high chromium grade, R20033, is also intended for hot

concentrated sulfuric acid. It is weldable and has a broader range of potential uses than do the high-silicon alloys.

Materials in the 5–7% molybdenum range are used for seawater service and chemical process vessels in general. Alloys N08367, S31254, and N08926 constitute the “6 moly” alloys. These have both corrosion resistance and cost intermediate between 316L and alloy C-276. All are readily fabricated and broadly available. Nitrogen in these alloys retards sigma formation, in spite of rather high Mo and moderate Ni levels. Prolonged exposure in the 1000–1800°F (540–980°C) temperature range may cause sigma-phase precipitation.

Alloys in the 13–16% Mo range include C-276, C-22, 59, C-2000, and 686. The latter four are regarded as improvements over C-276, with higher Cr for oxidizing environments. The newest, and possibly best, of the very high end nickel alloys, MAT 21, makes use of a tantalum addition, as well as 19% Mo.

Alloy selection for corrosive process environments is a complex process. It should include experience with similar equipment, extensive testing in the exact corrosive environment of interest, and detailed knowledge of the various alloys to be considered. Oftentimes, apparently minor contaminants can cause major changes in corrosion rates. One example is contamination of organic chlorides with small amounts of water. This can permit the organic compound to hydrolyze, forming hydrochloric acid. The HCl in turn may aggressively pit or stress corrode the standard 18–8 stainless steels. Other examples include the alloys B-2, 200, and 400, which contain no chromium. While they have excellent corrosion resistance in reducing environments, they have little or no resistance to oxidizing environments. Unexpected failures may therefore arise from contamination by small amounts of oxidizing salts (e.g., FeCl<sub>3</sub>, CuCl<sub>2</sub>, or NaClO<sub>3</sub>), or even dissolved oxygen. Titanium behaves in the opposite manner and requires the presence of oxidizing species to develop its protective oxide film.

## 10 WELDING<sup>8</sup>

There are some important distinctions between welding carbon steel and welding stainless steel. Alloys containing more than about 20% nickel have somewhat different requirements than the lower nickel austenitic stainless steels. There are specific issues regarding duplex stainless steels and weld fillers for the high-molybdenum grades.

### 10.1 Carbon Steel versus Stainless

Six important differences between welding the carbon or low-alloy structural steels and the austenitic stainless and nickel alloys are surface preparation, shielding gases, cold cracking versus hot cracking, distortion, penetration, and fabrication time.

**1. Surface Preparation.** When fabricating carbon steel, it is common practice to weld right over the scale (a so-called mill finish is a layer of blue-black oxide, or scale, on the metal surface), red rust, and even paint. The steel weld fillers normally contain sufficient deoxidizing agents, such as manganese and silicon, to reduce these surface iron oxides back to metallic iron. The resultant Mn–Si slag floats to the weld surface. Iron oxide, or scale, melts at a lower temperature, 2500°F (1371°C), than does the steel itself. One can see this in a

steel mill when a large ingot is removed from the soaking pit for forging—the molten scale literally drips off the white-hot steel.

Stainless steel, by contrast, must be clean and free of any black scale from hot rolling, forging, or annealing operations. Such scale is predominately chromium oxide. Normally, stainless is produced with a descaled white or bright finish. Stainless steel melts at a lower temperature than does its chromium oxide scale, and the stainless weld filler chemistry is not capable of reducing this scale back to metallic chromium. As a result, with gas-shielded processes it is difficult to get the weld bead to even “wet,” or stick to, a scaled piece of stainless.

The need to clean or grind down to bright metal is more likely to cause trouble when stainless is being joined to carbon steel. In this dissimilar metal joint it is necessary to grind that carbon steel to bright metal, on both sides of the joint, free of all rust, mill scale, grease, and paint. The preferred weld fillers for this particular joint, to minimize the hard martensitic layer on the steel side, are ENiCrFe-3-covered electrodes or ERNiCr-3 bare filler wire; E309 electrodes are commonly used but are not the optimum choice.

Both stainless and high-nickel alloys designed for corrosion resistance are produced to very low carbon contents, less than 0.03% and sometimes less than 0.01% carbon. Any higher carbon will reduce the metal's corrosion resistance. For this reason it is necessary to clean the alloy thoroughly of all grease and oil before welding. Also the very high nickel alloys, such as Monel 400 or commercially pure nickel 200/201, are very sensitive to weld cracking from the sulfur in oil or marking crayons.

Metallic zinc paint is a common way to protect structural steel from corrosion. Even a small amount of that zinc paint overspray on stainless will cause the stainless to crack badly when welded. Consider finishing all stainless welding before painting the structural steel in the area.

**2. Shielding Gases.** For gas-metal arc welding (GMAW, a.k.a. MIG) carbon steel the shielding gases are usually 95% argon 5% oxygen, 75% argon 25% carbon dioxide, or 100% CO<sub>2</sub>. While suitable for carbon or low-alloy steel welding wire, such gases are far too oxidizing for use with stainless or nickel alloys. It is not unknown to hear the complaint “clouds of red smoke are coming off when I weld this stainless . . . heavy spatter” and then learn that the shielding gas used was 75% argon 25% CO<sub>2</sub>. A fine gas for carbon steel but not for any stainless.

One exception to this high CO<sub>2</sub> prohibition is when using flux-cored wire, either stainless or nickel alloy. Some of these wires are specifically formulated to run best with 75% Ar 25% CO<sub>2</sub>.

Stainless and nickel alloys may be GMAW spray-arc welded using 100% argon shielding gas, though it is not necessarily the ideal choice. Stainless steels possess a passive chromium oxide film. The basis of stainless corrosion resistance, this film is not desirable when welding. Some 80% argon is necessary to get into a spray-transfer mode. Beyond this, a helium addition, up to about 20%, gives a hotter arc and helps break up the oxide film. A very slight amount of carbon dioxide, perhaps 1–2%, will prevent arc wander. Too much CO<sub>2</sub> may begin to add carbon to the weld, undesirable for corrosion resistance. Nitrogen may be added in gases specifically designed for welding the duplex stainless steels.

Pulse-arc welding is usually done with a 75% argon 25% helium mix. Short-circuiting arc transfer may be done with this 75% Ar–25% He mix but a 90% helium 7½% argon 2½% CO<sub>2</sub> “tri-mix” is more commonly used.

**3. Cold Cracking versus Hot Cracking.** Carbon steel weldments may harden, and crack, as they cool from welding. High hardness, and the resulting cracking, may occur when the steel contains more than 0.25% carbon. Alloying elements that increase hardenability, such as manganese, chromium, molybdenum, etc., can make steels of lower carbon content also harden. Hydrogen pickup from moisture in the air causes underbead cracking in steels that harden as they cool from welding. To prevent such cracking, the steel is usually preheated before welding. This retards the cooling rate of the weld and avoids martensite formation. Postweld heat treatment, or stress relief, is also applied to some steels, or for certain applications. The martensitic stainless steels behave in this fashion and because of their high hardenability are quite difficult to weld.

Austenitic stainless and nickel alloys do NOT harden, no matter how fast they cool from welding. So, it is not necessary to preheat austenitic stainless, nor to postweld heat treatment. Indeed preheating austenitic alloys, beyond what may be necessary to dry the metal, can be positively harmful. Stress relief 1100–1200°F (600–650°C) as applied to carbon steel is ineffective with stainless or nickel alloys and may damage the corrosion resistance of some grades.

Stainless steel weldments are usually quite resistant to cracking, unless contaminated, possibly by zinc or copper, more rarely by aluminum. A small amount of ferrite in the austenitic weld bead provides this hot cracking resistance.

High-nickel alloys are less forgiving and may be susceptible to cracking in restrained joints, including heavy sections. This is a hot tearing, not a cold crack. That is, the weld bead tears rather than stretching, as the bead contracts upon solidifying.

This hot tearing/hot cracking has nothing to do with hardness. The faster a nickel alloy weld freezes solid, the less time it spends in the temperature range where it can tear. For this reason preheating, which slows down the cooling rate, is actually harmful, as it permits more opportunity for hot tearing to occur.

**4. Distortion.** Stainless steel has poor thermal conductivity, only about one fourth that of ASTM A36 structural steel. This means the welding heat tends to remain concentrated, rather than spread out. Stainless also expands with heat about half again as much as does carbon steel. The combination of these two factors means that stainless or nickel alloy fabrications distort significantly more than similar designs in carbon steel.

Tack welds should be closer than with carbon steel and sequenced in a pattern, left side, right side, middle, etc. If the tacks are simply done in order from one end, the plate edges close up. To balance stresses, weld runs should be done symmetrically about the joint's center of gravity. Back step welding is helpful. This subject is well covered in Refs. 9 and 10.

Reducing heat input reduces the stresses and distortions from the welding operation. Heat into the workpiece is controlled by welding current, arc voltage, travel speed, and the specific welding process used. For the same amperes, volts and speed, submerged arc welding (SAW) transfers the most heat; shielded metal arc (SMAW), and gas–metal arc (GMAW) with argon shielding next and roughly

equivalent. Gas–tungsten arc welding (GTAW) can put the least heat into the work.

**5. Penetration.** There is a tendency to increase heat input with the stainless and high-nickel alloys. First, the weld fillers tend to be sluggish and not flow well, as compared with carbon steel. Second, the arc simply will not penetrate stainless steel as it does carbon steel. The higher the nickel, the less the penetration. Increasing welding current will not solve the problem, and may cause cracking in the higher nickel grades. Stainless, and especially nickel alloy, joint designs must be more open. The base metal should be single or double beveled, with a root gap, so that the weld metal may be placed in the joint.

**6. Fabrication Time.** Cleanliness, distortion control measures, maintaining low interpass temperatures, and even machining add up to more time spent fabricating stainless than carbon steel. A shop experienced with stainless may require 1.6 times as long to complete the same fabrication in stainless, as in carbon steel. A good carbon steel shop encountering stainless or nickel alloys for the first time may easily spend twice as long, maybe even three times as long, to do the stainless fabrication, as it would the same job in carbon steel.

## 10.2 Austenitic Alloys

The fundamental problem to be overcome in welding austenitic nickel bearing alloys is the tendency of the weld to hot tear upon solidification from the melt. This matter is readily handled in stainless steels of up to about 15% or so nickel. In these stainless grades the weld metal composition is adjusted, usually by slightly higher chromium and reduced nickel, to form a small amount of ferrite upon solidification. The amount of ferrite in the weld may be measured magnetically, and is reported as a ferrite number (FN). This ferrite acts to nullify the effects of the elements responsible for hot cracking in the Ni–Cr–Fe austenitics. These elements are chiefly phosphorus, sulfur, silicon, and boron. In higher nickel grades, about 20% nickel and over, it is metallurgically not possible to form any measurable amount of ferrite. Therefore other means of minimizing hot cracking must be used. Foremost among these is to use high purity raw materials in the manufacture of weld fillers. Simply reducing the amounts of harmful P, S, Si, and B in the weld metal improves its ability to make a sound weld. Phosphorus, in particular, must be kept below 0.015% in the weld wire itself. Certain alloy additions such as manganese, columbium (niobium), and molybdenum serve in one way or another to reduce the austenitic propensity for weld hot cracking. Manganese ranges from about 2% in AWS E310-15-covered electrodes to 8% in ENiCrFe-3-nickel-alloy-covered electrodes. Columbium at the 0.5% level, as in 347 or 20Cb-3 stainless, is harmful whereas 2–4% Cb is quite beneficial in many nickel base weld fillers. Molybdenum is not added with the intention of increasing weldability, nevertheless it does so. The 2% Mo contributes to 316L being the most weldable of the stainless steels, and 15% in C-276 accounts for the popularity of the various “C-type” electrodes in repair welding.

The distinction between the lower nickel stainless grades, which depend upon ferrite to ensure weldability, and the high-nickel alloys, which require high purity weld fillers, is an important one to remember. Most ferrite-containing (stainless)

weld fillers are useless with nickel alloy base metal, as dilution of the weld bead with nickel from the base metal eliminates this ferrite. Likewise a high purity nickel alloy weld filler, such as ER320LR, may not be quite so crack resistant when contaminated by phosphorus from use on 316L or carbon steel base metal.

### **Alloys under 20% Nickel**

Most austenitic grades containing less than 20% nickel are joined with weld fillers that utilize some ferrite, perhaps 4-12 FN, to ensure freedom from hot cracks. In practice, this means stainless steels up through 317LMN or 309S, both about 13% nickel. The 310S type stands in an odd position between the stainless and the nickel alloys, having neither ferrite nor any particular alloy addition to the weld metal to ensure sound welds. Not surprisingly, 310S welds have a reputation for fissuring.

### **Alloys over 20% Nickel**

Corrosion-resistant alloys in this category begin with the 18% nickel 254 SMO, for this and other “6 moly” grades are welded with an overmatching nickel alloy filler such as ERNiCrMo-3.

Other nickel alloys are joined with matching composition weld fillers modified only by restrictions on P, S, Si, and B. A minor amount of titanium may be added for deoxidation. Other fillers contain significant manganese or columbium to improve resistance to fissuring and hot cracking.

Such chemistry modifications are rarely as effective as is the use of ferrite in the lower nickel stainless weld fillers. Welding technique and attention to cleanliness, then, become increasingly important to ensure the soundness of fully austenitic welds. These techniques include bead contour and low interpass temperature. Reinforced, convex stringer beads are much more resistant to center-bead cracking than are shallow, concave beads. Interpass temperature for most nickel alloy weldments is kept below 300°F (150°C). Cleanliness includes NOT using oxygen additions to the GMAW shielding gases for nickel alloys.

It is worth repeating here that high-nickel alloys cannot be welded using stainless steel weld fillers. Stainless steel fillers (308, 309, etc.) depend upon a chemistry that will solidify from the melt as a duplex structure, containing a small amount of ferrite in with the austenite.

## **10.3 Duplex Stainless Steels<sup>11</sup>**

When welding duplex stainless the issues are maintaining the austenite–ferrite balance in the weldment and avoiding precipitation of nitrides and sigma. Rather high heat input is used to weld duplex, similar to welding 316L stainless. This is in contrast to the lower heat preferred with the high-nickel alloys. Low heat input is positively NOT desirable with a duplex, as it may not permit sufficient transformation of ferrite to austenite upon cooling. Current duplex weld fillers have nickel content somewhat increased over that of the base metal. This is to ensure that enough weld metal ferrite transforms to austenite, to maintain a balance of the two phases.

Toughness and critical pitting temperature of duplex weldments vary with the choice of welding process, in opposite directions. In order of increasing notch impact toughness: SMAW AC/DC, FCAW (flux cored arc welding), SMAW

DC-basis, SAW, GMAW argon shielding, GMAW 95AR 3He 2N<sub>2</sub> shielding, and GTAW. In order of increasing pitting resistance, as measured by critical pitting temperature: GTAW, GMAW, SAW, FCAW, SMAW DC-basis, and SMAW AC/DC.

#### 10.4 High-Molybdenum Alloys<sup>12</sup>

High-molybdenum-containing stainless and nickel alloys are welded with an overmatching filler metal. This is necessary to maintain corrosion resistance in the weld metal at least equal to the base metal. The reason is that molybdenum and chromium segregate as the weld metal solidifies from the melt. This leaves local areas with high, and with low, molybdenum. Pitting corrosion can start in the low-Mo area, with the pits eventually growing even into metal with high molybdenum. This occurs in alloys ranging from 316L to C-276, being more severe at higher alloy contents.

This matter began to receive attention when the 6% molybdenum stainless steels came on the market. If any of these 6% Mo grades are welded without filler metal, the result is a weld bead that may be as low as 3% Mo in areas. The end result can be that this weld has only the pitting corrosion resistance of 317L stainless. In the case of tubular products autogenously welded in production, a high-temperature anneal is used to homogenize the metal. In addition, a small amount of nitrogen, 3–5%, is added to the torch gas. Fabrications of thin sheet, which cannot be annealed after welding, should have this nitrogen addition to minimize the loss of corrosion. In addition, thin sheet welds solidify more quickly, hence the segregation is less severe.

In normal fabrication of a 6% molybdenum grade, alloy 625 (ERNiCrMo-3) filler metal is used. The weld metal contains 9% Mo. After welding, segregation causes some areas to have as little as 6% molybdenum. The result is that the alloy 625 weld bead has approximately the same corrosion resistance as the 6% molybdenum base metal. Higher alloy weld fillers, such as ERNiCrMo-10 or ERNiCrMo-14, may also be used, though the benefit may be more theoretical than real. ERNiCrMo-4 is not suggested, as it has 5% less chromium than does AL-6XN, for example. Since the mid-1980s nearly all of the 6% molybdenum alloy fabrications have been made, and put into service, using a 9% molybdenum weld filler.

ERNiCrMo-3 weld filler is widely available and is appropriate for welding lower alloys such as 317L, 317LMN, and 904L for chloride service. This molybdenum, and chromium, segregation problem exists with the 13–16% Mo nickel alloys as well. In this case there is not much choice in higher alloy weld fillers.

### 1 NATURE OF ALUMINUM ALLOYS

Aluminum alloys are broadly used in products and applications that touch us regularly in our daily lives, from aluminum foil for food packaging and easy-open aluminum cans for beverages to the structural members of the aircraft in which we travel. The broad use of aluminum alloys is dictated by a very desirable combination of properties, combined with the ease with which they may be produced in a great variety of forms and shapes.

The first step in becoming familiar with the opportunities to utilize aluminum alloys advantageously is to briefly note some of the basic characteristics of wrought aluminum alloys that make them desirable candidates for such a wide range of applications, as well as their limitations. Wrought alloys (those mechanically formed by rolling, forging, and extrusion into useful products) are addressed first, then cast alloys (those cast directly to the near-final finished shape).

For readers who are interested in a broader look at the aluminum industry, the publications of the Aluminum Association, Inc., are highly recommended, especially:

- D. G. Altenpohl, *Aluminum: Technology, Applications, and Environment*, The Aluminum Association, Washington, DC, and TMS, Warrendale, PA 1998

- *Aluminum Standards & Data (Standard and Metric Editions)*, The Aluminum Association, Inc., Washington, DC, published periodically
- *The Aluminum Design Manual*, The Aluminum Association, Inc., Washington, DC, 2000.

See the list of references at the end of the chapter for a more complete listing.

### 1.1 Advantages of Wrought Aluminum Alloys

1. *Corrosion Resistance.* As a result of a naturally occurring tenacious surface oxide film, many aluminum alloys provide exceptional resistance to corrosion in many atmosphere and chemical environments. Alloys of the 1xxx, 3xxx, 5xxx, and 6xxx systems are especially favorable in this respect and are even used in applications where they are in direct contact with seawater and antiskid salts. With some electrocoating enhancements (e.g., anodizing), the oxide coating can be thickened for even greater protection.

2. *Thermal Conductivity.* Aluminum and its alloys are good conductors of heat, and, while they melt at lower temperatures than steels, about 1000°F (about 535°C), they are slower to reach very high temperatures than steel in fire exposure.

3. *Electrical Conductivity.* Pure aluminum and some of its alloys have exceptionally high electric conductivity (i.e., very low electrical resistivity), second only to copper among common metals as conductors.

4. *Strength/Weight Ratio.* The combination of relatively high strength with low density means a high strength efficiency for aluminum alloys and many opportunities for replacement of heavier metals with no loss (and perhaps a gain) in load-carrying capacity. This characteristic, combined with the excellent corrosion resistance and recyclability, has led to aluminum's broad use in containers, aircraft, and automotive applications.

5. *Fracture Toughness and Energy Absorption Capacity.* Many aluminum alloys are exceptionally tough and excellent choices for critical applications where resistance to brittle fracture and unstable crack growth are imperatives. Alloys of the 5xxx series, for example, are prime choices for liquified natural gas (LNG) tankage. And special high-toughness versions of aircraft alloys, such as 2124, 7050, and 7475, replace the standard versions of these alloys for critical bulkhead applications.

6. *Cryogenic Toughness.* Aluminum alloys, especially of the 3xxx, 5xxx, and 6xxx series, are ideal for very low temperature applications because the ductility and toughness as well as strength of many alloys at subzero temperatures are as high as or higher than at room temperature, even down to near absolute zero.

7. *Fatigue Strength.* On an efficiency basis (strength to density) the fatigue strengths of many aluminum alloys are comparable to those of steels.

8. *Modulus of Elasticity.* Aluminum alloys have elastic moduli about one third those of steels (about 10,000,000 psi vs. about 30,000,000 psi), so they absorb about three times as much elastic energy upon deformation to the same stress. They also deflect three times more under load (see Section 1.3).

9. *Workability.* Aluminum alloys are readily workable by a great variety of metal-working technologies and especially amenable to extrusion (the process

of forcing heated metal through shaped dies to produce specific shaped sections). This enables aluminum to be produced in a remarkable variety of shapes and forms in which the metal can be placed in locations where it can most efficiently carry the applied loads.

**10. *Ease of Joining.*** Aluminum alloys may be joined by a very broad variety of commercial methods including welding, brazing, soldering, riveting, bolting and even nailing in addition to an unlimited variety of mechanical procedures. Welding, while considered difficult by those familiar only with joining steel and who try to apply the same techniques to aluminum, is particularly easy when performed by proven techniques such as gas-metal arc welding (GMAW or MIG) or gas-tungsten arc welding (GTAW).

**11. *Recyclability.*** Aluminum and its alloys are among the easiest to recycle of any structural materials. And they are recyclable in the truest sense, unlike materials that are reused but in lower quality products: Aluminum alloys may be recycled *directly* back into the same high-quality products like rigid container sheet (cans) and automotive components.

## 1.2 Advantages of Cast Aluminum Alloys

The desirable characteristics of wrought alloys are also generally applicable to cast alloys, but in fact the choice of one casting alloy or another tend to be more often made on the basis of their relative abilities to meet one or more of the following characteristics:

*Ease of Casting.* Many aluminum casting alloys have relatively high-silicon contents that provide excellent flow characteristics during casting, enabling them to be utilized for large and complex castings (even complete engines, for example). Relatively minute details in the shape of the casting can be accurately and reliably replicated.

*High Strength.* Many aluminum casting alloys respond to heat treatment following casting and achieve relatively high levels of strength and excellent strength/weight ratios. With careful design of molds, high chill rates can be assured and both high strength and high toughness can be achieved.

*Quality of Finish.* By proper selection of aluminum casting alloy, extremely fine surface quality can be achieved. While such alloys typically require more attention to casting practice typically, they are widely used in applications where the finished casting surface mirrors the finish needed in surface.

Unfortunately few casting alloys possess all three characteristics, but some generalizations may be made:

1. The high-silicon 3xx.x series are outstanding with respect to ease of casting as the relatively high silicon contents lend a characteristic of good flow and mold filling capability. As a result, the 3xx.x series are the most widely used and especially chosen for large and very complex casting.
2. The 2xx.x alloys typically provide the very highest strengths but are more difficult to cast and lack good surface characteristics. Therefore their use

is usually limited to situations where expert casting techniques can be applied and where strength and toughness are at a premium, as in the aerospace industry.

3. The 5xx.x and 7xx.x series are noteworthy for the fine finish they provide, but they are more difficult to cast than the 3xx.x series and so are usually limited to those applications where that finish is paramount. A good example is the use of 7xx.x alloys for bearings.

### 1.3 Limitations of Wrought and Cast Aluminum Alloys

There are several characteristics of aluminum alloys that require special attention in alloy selection or design:

1. *Moduli of Elasticity.* As noted earlier, the elastic moduli of aluminum alloys are about one third those of steel. In applications such as bridges, where some designs may be deflection critical, consideration should be given to the fact that aluminum alloys will deflect about three times more than comparably sized steel members; in order to compensate for this aluminum members subject to bending loads are usually made deeper or thicker in their upper and lower extremities to reduce stresses and/or deflections.

2. *Melting Temperature.* Aluminum alloys melt at about 1000°F (535°C), well below where steels melt, and so they should not be selected for applications such as flue pipes and fire doors where the low melting point may result in unsatisfactory performance. The useful limit of high-temperature structural application of aluminum alloys is about 500°F (about 260°C) for conventional alloys or about 600°F (315°C) for alumina-enhanced alloys. It is useful to note that even in the most intense fires, aluminum alloys do not burn; they are rated noncombustible in all types of fire tests and achieve the highest ratings in flame-spread tests. Further, as noted earlier, they are slower to reach high temperatures in fires than other metals such as steels because of their higher thermal conductivity and emissivity. Nevertheless, they should not be used where service requirements include structural strength above 500°F or exposure above 1000°F.

3. *Stress–Corrosion Susceptibility of Some Alloys.* Some aluminum alloys, notably the 2xxx and 7xxx alloys, when stressed perpendicular to the major plane of grain flow (i.e., in the short-transverse direction) may be subject to intergranular stress–corrosion cracking (SCC) unless they have been given a special thermal treatment to reduce or eliminate this type of behavior. If short transverse stresses are anticipated in relatively thick components, 2xxx alloys should only be utilized in the T6- or T8-type tempers (not T3- or T4-type tempers), and 7xxx alloys should only be used in the T73-type tempers (not T6- or T8-type tempers). Similarly, 5xxx alloys with more than 3% Mg should not be used in applications where a combination of high stress and high temperature will be experienced over a long period of time (more than several hundred hours), because some susceptibility to SCC may be encountered (i.e., the alloys may become “sensitized”); for applications where temperatures above about 150°F are likely to be encountered for long periods, the use of 5xxx alloys with 3% or less Mg is recommended.

4. *Mercury Embrittlement.* Aluminum alloys should never be used when they may be in direct contact with liquid or vaporized mercury; severe grain-

boundary embrittlement may result. This is an unlikely exposure for the vast majority of applications, but in any instance where there is the possibility of mercury being present, the use of aluminum alloys should be avoided.

## 2 DESIGNATION SYSTEMS

One advantage in using aluminum alloys and tempers is the universally accepted and easily understood alloy and temper systems by which they are known. It is extremely useful for both secondary fabricators and users of aluminum products and components to have a working knowledge of the those designation systems. The alloy system provides a standard form of alloy identification that enables the user to understand a great deal about the chemical composition and characteristics of the alloy, and similarly, the temper designation system permits one to understand a great deal about the way in which the product has been fabricated.

The alloy and temper designation systems in use today for wrought aluminum were adopted by the aluminum industry in about 1955, and the current system for cast system was developed somewhat later. The aluminum industry managed the creation and continues the maintenance of the systems through its industry organization, The Aluminum Association. The alloy registration process is carefully controlled and its integrity maintained by the Technical Committee on Product Standards of the Aluminum Association, made up of industry standards experts. Further, as noted earlier, the Aluminum Association designation system is the basis of the American National Standards Institute (ANSI) standards, incorporated in ANSI H35.1<sup>1</sup> and, for the wrought alloy system at least, is the basis of the near-worldwide International Accord on Alloy Designations.<sup>2</sup>

The Aluminum Association Alloy and Temper Designation Systems covered in ANSI H35.1 and aluminum standards and data<sup>3</sup> are outlined in this chapter.

### 2.1 Wrought Aluminum Alloy Designation System

The Aluminum Association Wrought Alloy Designation System consists of four numerical digits, sometimes with alphabetic prefixes or suffices, but normally just the *four* numbers:

- The *first* digit defines the major alloying class of the series, starting with that number.
- The *second* defines variations in the original basic alloy; that digit is always a zero (0) for the original composition, a one (1) for the first variation, a two (2) for the second variation, and so forth; variations are typically defined by differences in one or more alloying elements of 0.15–0.50% or more, depending upon the level of the added element.
- The *third and fourth* digits designate the specific alloy within the series; there is no special significance to the values of those digits except in the 1xxx series (see below), nor are they necessarily used in sequence.

Table 1 shows the meaning of the first of the four digits in the alloy designation system. The alloy family is identified by that number and the associated main alloying ingredient(s), with three exceptions:

**Table 1 Main Alloying Elements in Wrought Alloy Designation System**

| Alloy | Main Alloying Element                             |
|-------|---------------------------------------------------|
| 1000  | Mostly pure aluminum; no major alloying additions |
| 2000  | Copper                                            |
| 3000  | Manganese                                         |
| 4000  | Silicon                                           |
| 5000  | Magnesium                                         |
| 6000  | Magnesium and silicon                             |
| 7000  | Zinc                                              |
| 8000  | Other elements (e.g., iron or tin)                |
| 9000  | Unassigned                                        |

- Members of the 1000 series family are commercially pure aluminum or special purity versions, and as such do not typically have any alloying elements intentionally added; however they do contain minor impurities that are not removed unless the intended application requires it.
- The 8000 series family is an “other elements” series, comprised of alloys with rather unusual major alloying elements such as iron and nickel.
- The 9000 series is unassigned.

The major benefits of understanding this designation system are that one can tell a great deal about the alloy just from knowing to which series it belongs.

- As indicated earlier, the 1xxx series are pure aluminum and its variations; compositions of 99.0% or more aluminum are by definition in this series. Within the 1xxx series, the last two of the four digits in the designation indicate the minimum aluminum percentage. These digits are the same as the two digits to the right of the decimal point in the minimum aluminum percentage specified for the designation when expressed to the nearest 0.01%. As with the rest of the alloy series, the second digit indicates modifications in impurity limits or intentionally added elements. Compositions of the 1xxx series do not respond to any solution heat treatment but may be strengthened modestly by strain hardening.
- The 2xxx series alloys have copper as their main alloying element and, because it will go in significant amounts into solid solution in aluminum, they will respond to solution heat treatment; they are referred to as heat treatable.
- The 3xxx series alloys are based on manganese and are strain hardenable; they do not respond to solution heat treatment.
- The 4xxx series alloys are based on silicon; some alloys are heat treatable, others are not, dependent upon the amount of silicon and the other alloying constituents.
- The 5xxx series alloys are based on magnesium and are strain hardenable, not heat treatable.

- The 6xxx series alloys have both magnesium and silicon as their main alloying elements; these combine as magnesium silicide ( $\text{Mg}_2\text{Si}$ ) following solid solution, and so the alloys are heat treatable.
- The 7xxx series alloys have zinc as their main alloying element, often with significant amounts of copper and magnesium, and they are heat treatable.
- The 8xxx series contain one or more of several less frequently used major alloying elements like iron or tin; their characteristics depend on the major alloying element(s).

The compositions of a representative group of widely used commercial wrought aluminum alloys are given in Table 2, taken from *Aluminum Standards & Data*<sup>3</sup> and other Aluminum Association publications.

## 2.2 Cast Aluminum Alloy Designation System

The designation system for cast aluminum alloys is similar in some respects to that for wrought alloys but has a few very important differences as noted by the following description.

Like the wrought alloy system, the cast alloy designation system also has four digits, but differs from the wrought alloy system in that a decimal point is used between the third and fourth digits to make clear that these are designations to identify alloys in the form of castings or foundry ingot.

As for the wrought alloy designation system, the various digits of the cast alloy system convey information about the alloy:

- The first digit indicates the alloy group, as can be seen in Table 3. For 2xx.x through 8xx.x alloys, the alloy group is determined by the alloying element present in the greatest mean percentage, except in cases in which the composition being registered qualifies as a modification of a previously registered alloy. Note that in Table 3, the 6xx.x series is shown last and for cast alloys is designated as the unused series.
- The second and third digits identify the specific aluminum alloy or, for the aluminum 1xx.x series, indicate purity. If the greatest mean percentage is common to more than one alloying element, the alloy group is determined by the element that comes first in sequence. For the 1xx.x group, the second two of the four digits in the designation indicate the minimum aluminum percentage. These digits are the same as the two digits to the right of the decimal point in the minimum aluminum percentage when expressed to the nearest 0.01%.
- The fourth digit indicates the product form: xxx.0 indicates castings, and xxx.1 for the most part indicates ingot having limits for alloying elements the same as those for the alloy in the form of castings. A fourth digit of xxx.2 may be used to indicate that the ingot has composition limits that differ from but fall within the xxx.1 limits; this typically represents the use of tighter limits on certain impurities to achieve specific properties in the cast product produced from that ingot.

Table 2 Nominal Compositions of Wrought Aluminum Alloy<sup>a</sup>

| Alloy | Percent of Alloying Elements <sup>b</sup> |        |           |           |          |        |      |          | Notes <sup>c</sup> |
|-------|-------------------------------------------|--------|-----------|-----------|----------|--------|------|----------|--------------------|
|       | Silicon                                   | Copper | Manganese | Magnesium | Chromium | Nickel | Zinc | Titanium |                    |
| 1060  | —                                         | —      | —         | —         | —        | —      | —    | —        | 1                  |
| 1100  | —                                         | —      | —         | —         | —        | —      | —    | —        | 1                  |

<sup>a</sup>Based upon industry handbooks.<sup>3,4</sup> Consult those references for specified limits. Values are nominal, i.e., middle range of limits for elements for which a composition range is specified.

<sup>b</sup>Aluminum and normal impurities constitute remainder.

- <sup>c</sup>
1. Percent minimum aluminum—for 1060: 99.60%; for 1100: 99.00%; for 1145: 99.45%; for 1350: 99.50%. Also, for 1100, 0.12% iron.
  2. Formerly designated EC.
  3. Also contains 0.05% vanadium (max.).
  4. Also contains 0.40% lead and 0.4% bismuth.
  5. This alloy has tighter limits on impurities than does its companion alloy (2024 or 7075).
  6. Also contains 1.0% lithium, 0.42% silver, and 0.12% zirconium.
  7. Also contains 0.10% vanadium plus 0.18% zirconium.
  8. Also contains 1.1% iron.
  9. Also contains 0.55% lead and 0.55% bismuth.
  10. Also contains 0.14% zirconium.
  11. Also contains 0.12% zirconium.
  12. Also contains 0.05% max. vanadium plus 0.03% max. gallium.
  13. Also contains 0.7% iron.
  14. Also contains 2.4% lithium plus 0.10% zirconium.

Table 3 Cast Alloy Designation System

| Alloy | Main Alloying Element                       |
|-------|---------------------------------------------|
| 1xx.x | Pure aluminum, 99.00% max.                  |
| 2xx.x | Copper                                      |
| 3xx.x | Silicon, with added copper and/or magnesium |
| 4xx.x | Silicon                                     |
| 5xx.x | Magnesium                                   |
| 7xx.x | Zinc                                        |
| 8xx.x | Tin                                         |
| 9xx.x | Other elements                              |
| 6xx.x | Unused series                               |

A letter before the numerical designation indicates a modification of the original alloy or an impurity limit. These serial letters are assigned in alphabetical sequence starting with A, but omitting I, O, Q, and X, with X being reserved for experimental alloys. Note that explicit rules have been established for determining whether a proposed composition is a modification of an existing alloy or if it is a new alloy.

Experimental alloys of either the wrought or cast series are indicated by the addition of the prefix X. The prefix is dropped when the alloy is no longer experimental. However, during development and before an alloy is designated as experimental, a new composition may be identified by a serial number assigned by the originator. Use of the serial number is discontinued when the composition is registered with the Aluminum Association, Inc., and the ANSI H35.1 designation is assigned.

The compositions of a representative group of widely used commercial cast aluminum alloys are given in Table 4, taken from *Standards for Aluminum Sand and Permanent Mold Castings*<sup>5</sup> and other Aluminum Association and aluminum casting industry publications.

### 2.3 Aluminum Alloy Temper Designation System

The temper designation is always presented immediately following the alloy designation (see Sections 2.1 and 2.2), with a dash (-) between the two, e.g., 2014-T6.

The first character in the temper designation is a capital letter indicating the general class of treatment as follows:

*F* = *As-Fabricated*. Applies to wrought or cast products made by shaping processes in which there is no special control over thermal conditions or strain-hardening processes employed to achieve specific properties. For wrought alloys there are no mechanical property limits associated with this temper, though for cast alloys there may be.

*O* = *Annealed*. Applies to wrought products that are annealed to obtain the lower strength temper, usually to increase subsequent workability, and to cast products that are annealed to improve ductility and dimensional stability. The O may be followed by a digit other than zero.

*H* = *Strain Hardened*. Applies to products that have their strength increased by strain hardening. They may or may not have supplementary thermal treatments to produce some reduction in strength. The H is always followed by two or more digits.

*W* = *Solution Heat treated*. Applies only to alloys that age spontaneously after solution heat treating. This designation is specific only when digits are used in combination with W to indicate the period of natural aging, viz. W  $\frac{1}{2}$  h.

*T* = *Thermally Treated to Produce Stable Tempers other Than F*. Applies to products that are thermally treated, with or without supplementary strain hardening, to produce stable tempers. The T is always followed by one or more digits.

The most widely used temper designations above are the H and T categories, and these are always followed by from one to four numeric digits that provide

Table 4 Nominal Compositions of Aluminum Alloy Castings<sup>a</sup>

| Alloy  | Percent of Alloying Elements <sup>b</sup> |        |           |           |          |        |      |          | Notes <sup>c</sup> |
|--------|-------------------------------------------|--------|-----------|-----------|----------|--------|------|----------|--------------------|
|        | Silicon                                   | Copper | Manganese | Magnesium | Chromium | Nickel | Zinc | Titanium |                    |
| 201.0  | —                                         | 4.6    | 0.35      | 0.35      | —        | —      | —    | 0.25     | 1                  |
| 204.0  | —                                         | 4.6    | —         | 0.25      | —        | —      | —    | —        |                    |

**Table 4 (Continued)**

<sup>a</sup>Based upon industry handbooks,<sup>5–8</sup> consult those references for specified limits. Values are nominal, i.e., average of range of limits for elements for which a range is shown; values are representative of separately cast test bars, not of specimens taken from commercial castings.

<sup>b</sup>Aluminum and normal impurities constitute remainder.

- <sup>c</sup>
1. Also contains 0.7% silver.
  2. Also contains 1.2% iron.
  3. Also contains 0.10% vanadium and 0.18% zirconium.
  4. Impurity limits are much lower for this alloy than for alloy listed above it.
  5. Also contains 0.055% beryllium.
  6. Also contains up to 2.0% total Iron.
  7. Also contains 0.005% beryllium and 0.005% boron.
  8. Also contains 1.0 iron.
  9. Also contains 6.2% tin.

more detail about how the alloy has been fabricated. It is beyond the scope of this volume to describe the system in further detail and the reader is referred to refs. 1, 4, and 5 for additional needed information.

### 3 PROPERTIES OF ALUMINUM ALLOYS

The properties of a representative group of wrought aluminum alloys are shown in Tables 5 and 6. The properties of a representative group of cast aluminum alloys are shown in Tables 7 and 8.

### 4 APPLICATIONS OF ALUMINUM ALLOYS

There are at least two approaches to overviewing important applications of aluminum alloys: *by alloy class*, as initiated in Sections 1.1 and 1.2 and carried out in greater detail below, and *by type of application*. We will consider both approaches in the information below, reviewing by alloy class in Section 4.1 and by application in Section 4.2.

All photographs in this chapter are courtesy of the Aluminum Association, Inc. For a more complete discussion of these and other applications of aluminum alloys, the reader is referred to D. G. Altenpohl's very complete treatise on the aluminum industry, *Aluminum: Technology, Applications, and Environment*.<sup>9</sup>

#### 4.1 Applications by Alloy Class

##### Wrought Alloys

**1xxx: Pure Al.** The major characteristics of the 1xxx series are:

- Strain hardenable
- Exceptionally high formability, corrosion resistance, and electrical conductivity
- Typical ultimate tensile strength range: 10–27 ksi
- Readily joined by welding, brazing, soldering

The 1xxx series represents the commercially pure aluminum, ranging from the baseline 1100 (99.00% min. Al) to relatively purer 1050/1350 (99.50% min.

Table 5 Typical Mechanical Properties of Wrought Aluminum Alloys<sup>a</sup>

| Alloy & Temper | Tension                       |                            |                      |                    | Hardness<br>Brinell<br>Number<br>(500 kg/10 mm) | Shear<br>Ultimate<br>Strength<br>(ksi) | Fatigue<br>Endurance<br>Limit <sup>d</sup><br>(ksi) | Modulus <sup>e</sup><br>of<br>Elasticity<br>(10 <sup>3</sup> ksi) |
|----------------|-------------------------------|----------------------------|----------------------|--------------------|-------------------------------------------------|----------------------------------------|-----------------------------------------------------|-------------------------------------------------------------------|
|                | Ultimate<br>Strength<br>(ksi) | Yield<br>Strength<br>(ksi) | Elongation (%)       |                    |                                                 |                                        |                                                     |                                                                   |

<sup>a</sup>Based upon industry handbooks.<sup>1,16,17</sup> Consult those references for limits. For tensile yield strengths, offset = 0.2%.

<sup>b</sup>Elongation measured over a 2 in. gauge length on  $\frac{1}{16}$ -in thick sheet-type specimens.

<sup>c</sup>Elongation measured over 2 in. gauge length (4D) in  $\frac{1}{2}$ -in. diameter specimens.

<sup>d</sup>Based on 500,000,000 cycles of completely reversed stress using R. R. Moore type of machines and specimens.

<sup>e</sup>Average of tension and compression moduli; compressive modulus is nominally about 2% greater than the tension modulus.

<sup>f</sup>Measured over a 10-in. gauge length in wire.

<sup>g</sup>At 10<sup>7</sup> cycles with flexural fatigue specimens.

Table 6 Typical Mechanical Properties of Wrought Aluminum Alloys—Metric<sup>a</sup>

Table 6 (Continued)

<sup>a</sup>Based upon industry handbooks.<sup>1,16,17</sup> Consult those references for limits. For tensile yield strengths, offset = 0.2%.

<sup>b</sup>Elongation measured over a 500-mm. gauge length on 1.60-mm thick sheet-type specimens.

<sup>c</sup>Elongation measured over 500-mm gauge length (5D) in 12.5-mm diameter specimens.

<sup>d</sup>Based on 500,000,000 cycles of completely reversed stress using R.R. Moore type of machines and specimens.

<sup>e</sup>Average of tension and compression moduli; compressive modulus is nominally about 2% greater.

<sup>f</sup>Measured over a 250-mm gauge length in wire.

<sup>g</sup>At 10<sup>7</sup> cycles with flexural fatigue specimens.

Table 7 Typical Mechanical Properties of Wrought Aluminum Alloy Castings<sup>a</sup>

<sup>a</sup>Based upon industry handbooks.<sup>5-8</sup> Consult those references for limits. Values are representative of separately cast test bars, not of specimens taken from commercial castings. For tensile yield strengths, offset = 0.2%.

<sup>b</sup>Based on 500,000,000 cycles of completely reversed stress using R. R. Moore type of machines and specimens.

<sup>c</sup>Average of tension and compression moduli; compressive modulus is nominally about 2% greater than the tension modulus.

Table 8 Typical Mechanical Properties of Aluminum Alloy Castings—Metric<sup>a</sup>

<sup>a</sup>Based upon industry handbooks.<sup>5–8</sup> Consult those references for limits. Values are representative of separately cast test bars, not of specimens taken from commercial castings. For tensile yield strengths, offset = 0.2%.

<sup>b</sup>Based on 500,000,000 cycles of completely reversed stress using R. R. Moore type of machines and specimens.

<sup>c</sup>Average of tension and compression moduli; compressive modulus is nominally about 2% greater.

Al) and 1175 (99.75 % min. Al). The 1xxx series are strain hardenable but would not be used where strength is a prime consideration.

The primary uses of the 1xxx series would be applications where the combination of extremely high corrosion resistance and formability are required, e.g., foil and strip for packaging (Fig. 1), chemical equipment, tank car or truck bodies, spun hollowware, and elaborate sheet metal work.

Electrical applications are one major use of the 1xxx series, primarily 1350, which has relatively tight controls on those impurities that might lower electrical conductivity. As a result, an electrical conductivity of 62% of the International Annealed Copper Standard (IACS) is guaranteed for this material, which, combined with the natural light weight of aluminum, means a significant weight and therefore cost advantage over copper in electrical applications (Fig. 2).

**Fig. 1** Reynolds Heavy Duty Foil product, an example of aluminum food wrapping products made of various grades of 1xxx commercially pure aluminum.

**2xxx: Al–Cu Alloys.** The major characteristics of the 2xxx series are:

- Heat treatable
- High strength, at room and elevated temperatures
- Typical ultimate tensile strength range: 27–62 ksi
- Usually joined mechanically but some alloys are weldable

The 2xxx series are heat treatable and possess in individual alloys good combinations of high strength (especially at elevated temperatures), toughness, and, in specific cases, weldability. They are not as resistant to atmospheric corrosion as several other series and so are usually painted or clad for added protection.

The higher strength 2xxx alloys are widely used for aircraft (2024) and truck body (2014) applications, where they are generally used in bolted or riveted wing (Fig. 3) or fuselage (Fig. 4) construction. Some specific alloys in the series (e.g., 2219 and 2048) are readily joined by gas–metal arc (GMAW) or gas tungsten arc (GTAW) welding, and so are used for aerospace applications where that is the preferred joining method.

Alloy 2195 is a new Li-bearing aluminum alloy providing very high modulus of elasticity along with higher strength and comparable weldability to 2219 for space applications (Fig. 5).

For applications requiring very high strength plus high fracture toughness, there are high-toughness versions of several of the alloys (e.g., 2124, 2324, 2419) that have tighter control on the impurities that may diminish resistance to unstable fracture, all developed specifically for the aircraft industry.

**Fig. 2** Aluminum electrical bus bar installation with 1350 bus bar.

Alloys 2011, 2017, and 2117 are widely used for fasteners and screw-machine stock.

**3xxx: Al-Mn Alloys.** The major characteristics of the 3xxx series are:

- High formability and corrosion resistance with medium strength
- Typical ultimate tensile strength range: 16–41 ksi
- Readily joined by all commercial procedures

The 3xxx series are strain hardenable, have excellent corrosion resistance, and are readily welded, brazed, and soldered.

Alloy 3003 is widely used in cooking utensils and chemical equipment because of its superiority in handling many foods and chemicals, and in builders'

**Fig. 3** Aircraft wing and fuselage structure includes extrusions and plate of 2xxx alloys like 2024, 2124, and 2618 and 7xxx alloys like 7050 and 7475. External sheet skin may be alclad 2024, 2524, 2618, or 7475; the higher purity cladding provides corrosion protection to the Al-Cu and Al-Zn-Mg alloys that may darken with age otherwise.

**Fig. 4** Heavy dump and tank trucks and trailer trucks employ high-strength 2xxx or 6xxx extrusions for their structural members and tough 5xxx alloy sheet and plate for their load-carrying components.

hardware because of its superior corrosion resistance. Alloy 3105 is a principal for roofing and siding.

Because of the ease and flexibility of joining, 3003 and other members of the 3xxx series are widely used in sheet and tubular form for heat exchangers in vehicles and power plants (Fig. 6).

Alloy 3004 and its modification 3104 are the principals for the bodies of drawn and ironed can bodies for beverage cans for beer and soft drinks (Fig. 7). As a result, they are among the most used individual alloys in the aluminum system, in excess of 3.5 billion pounds per year.

**4xxx: Al-Si Alloys.** The major characteristics of the 4xxx series are:

- Heat treatable
- Good flow characteristics, medium strength

**Fig. 5** Fuel tanks and booster rockets such as those of the Space Shuttle are 2xxx alloys, originally 2219 and 2419, now Al–Li “Weldalite” alloy 2195.

- Typical ultimate tensile strength range: 25–55 ksi
- Easily joined, especially by brazing and soldering

There are two major uses of the 4xxx series, both generated by their excellent flow characteristics provided by their relatively high silicon contents. The first is for forgings: the workhorse alloy is 4032, a medium high-strength, heat-treatable alloy used principally in applications such as forged aircraft pistons. The second major application is a weld filler alloy; here the workhorse is 4043, used for gas–metal arc (GMA) and gas–tungsten arc (GTA) welding 6xxx alloys for structural and automotive applications.

As noted, the same characteristic leads to both types of application: good flow characteristic provided by the high-silicon content. In the case of forgings, this ensures the complete and precise filling of complex dies; in the case of welding, it ensures complete filling of grooves in the members to be joined. For the same reason, other variations of the 4xxx alloys are used for the cladding on brazing sheet, the component that flows to complete the bond.

**5xxx: Al–Mg Alloys.** The major characteristics of the 5xxx series are:

- Strain hardenable
- Excellent corrosion resistance, toughness, weldability; moderate strength
- Building and construction, automotive, cryogenic, marine applications
- Typical ultimate tensile strength range: 18–51 ksi

**Fig. 6** Alloy 3003 tubing in large commercial power plant heat exchanger.

Al-Mg alloys of the 5xxx series are strain hardenable and have moderately high strength, excellent corrosion resistance even in saltwater, and very high toughness even at cryogenic temperatures to near absolute zero. They are readily welded by a variety of techniques, even at thicknesses up to 20 cm.

As a result, 5xxx alloys find wide application in building and construction (Fig. 8), highways structures including bridges (Fig. 9), storage tanks and pressure vessels, cryogenic tankage, and systems for temperatures as low as  $-459^{\circ}\text{F}$  ( $-270^{\circ}\text{C}$ , near absolute zero), transportation (Fig. 10), and marine applications (Fig. 11), including offshore drilling rigs (Fig. 12).

Alloys 5052, 5086, and 5083 are the workhorses from the structural standpoint, with increasingly higher strength associated with the increasingly higher

**Fig. 7** Bodies of most beverage cans are alloy 3004, the ends are 5182, making it the largest volume alloy combination in the industry.

Mg content. Specialty alloys in the group include 5182, the beverage can end alloy (Fig. 7), and thus among the largest in tonnage; 5754 for automotive body frames and panels (Fig. 13); and 5252, 5457, and 5657 for bright trim applications, including automotive trim.

Care must be taken to avoid use of 5xxx alloys with more than 3% Mg content in applications where they receive continuous exposure to temperatures above 100°C (212°F). Such alloys may become sensitized and susceptible to stress corrosion cracking. For this reason, alloys such as 5454 and 5754 are recommended for applications where high-temperature exposure is likely.

**6xxx: Al–Mg–Si Alloys.** The major characteristics of the 6xxx series are:

- Heat treatable
- High corrosion resistance, excellent extrudability; moderate strength
- Typical ultimate tensile strength range: 18–58 ksi
- Readily welded by GMAW and GTAW methods

The 6xxx alloys are heat treatable and have moderately high strength coupled with excellent corrosion resistance. A unique feature is their great extrudability, making it possible to produce in single shapes relatively complex architectural forms and also to design shapes that put the majority of the metal where it will most efficiently carry the highest tensile and compressive stresses (Fig. 14). This

**Fig. 8** Sheet of 5xxx alloys often forms the surface of geodesic dome structures, as in these examples of (a) a water treatment plant and (b) a wide-span arena roof. The structural supports are typically 6061 or 6063 extruded shapes or tubular members.

is a particularly important advantage for architectural and structural members where stiffness is important.

Alloy 6063 is perhaps the most widely used because of its extrudability; it is not only the first choice for many architectural and structural members, it has been the choice for the Audi automotive space frame members. A good example of its structural use was the all-aluminum bridge structure in Foresmo, Norway (Fig. 9); it was prefabricated in a shop and erected on the site in only a few days.

**Fig. 9** The Foresmo bridge in northern Norway is an excellent example of the use of Al-Mg alloys for built-up girder systems; these photos illustrate a major advantage of replacement aluminum bridges: the ability to prefabricate the spans, (a) transport them, and (b) erect them in place quickly, minimizing the disruption to traffic.

Higher strength alloy 6061 extrusions and plate find broad use in welded structural members such as automotive, truck (Fig. 4), and marine frames, railroad cars, and pipelines. Alloys like 6111 provide a fine combination of strength and formability, useful for external automotive panels (Fig. 13b).

Among specialty alloys in the series: 6066-T6, with high strength for forgings; 6071 for the highest strength available in 6xxx extrusions; and 6101 and 6201 for high-strength electrical bus and electrical conductor wire, respectively.

**Fig. 10** Alloy 5454 has been widely used for railcar body construction where heavy loads, such as coal, and potentially high temperatures, may be involved.

**7xxx: Al–Zn Alloys.** The major characteristics of the 7xxx series are:

- Heat treatable
- Very high strength; special high toughness versions
- Typical ultimate tensile strength range: 32–88 ksi
- Mechanically joined

The 7xxx alloys are heat treatable and, among the Al–Zn–Mg–Cu versions in particular, provide the highest strengths of all aluminum alloys. These alloys are not considered weldable by commercial processes, and are regularly used with riveted construction.

The widest application of the 7xxx alloys has historically been in the aircraft industry (Fig. 3), where fracture-critical design concepts have provided the impetus for the high-toughness alloy development. There are several alloys in the series that are produced especially for their high toughness, notably 7050, 7150, 7175, and 7475; for these alloys, controlled impurity levels, particularly of Fe and Si, maximize the combination of strength and fracture toughness. Forgings of these alloys (Fig. 15) are often used for large structural members in aircraft.

The high-strength/density combination for 7075-T73 (and 2014-T6) have made them choices for drill pipe where the long lengths needed for deep wells require lightweight alloys.

The atmospheric corrosion resistance of the 7xxx alloys is not as high as that of the 5xxx and 6xxx alloys, so in such service they are usually coated or, for sheet and plate, used in an alclad version. Also, special tempers have been developed to improve their resistance to exfoliation and stress–corrosion cracking, the T76 and T73 types, respectively. These tempers are especially recom-

**Fig. 11** High-speed single-hull ships (a) like the *Proserpio* employ 5083 or 5383-H113/H321 machined plate for hulls, (b) internal hull stiffeners, decking, and superstructure.

**Fig. 12** Demands of the superstructures of offshore oil rigs in high humidity and water exposure are met with 5454, 5086, and 5083 Al-Mg alloy welded construction.

mended in situations where there may be high short transverse (through the thickness) stresses present during exposure to atmospheric or more severe environments.

The Cu-free 7xxx alloys have lower strength but are tougher and are both readily extrudable and weldable, so alloys like 7005 and 7029 find their way into applications like guard rail and automotive and truck bumpers.

***8xxx: Alloys with Al + Other Elements (Not Covered by Other Series).***

The major characteristics of the 8xxx series are:

- Heat treatable
- High conductivity, strength, hardness
- Typical ultimate tensile strength range: 17–35 ksi

The 8xxx series is used for those alloys with lesser-used alloying elements such as Fe, Ni, and Li. Each is used for the particular characteristics it provides the alloys.

Fe and Ni provide strength with little loss in electrical conductivity and so are used in a series of alloys represented by 8017 for conductors.

Lithium in alloy 8090 provides exceptionally high strength and modulus, and so this alloy is used for aerospace applications where increases in stiffness combined with high strength reduces component weight.

### **Cast Alloys**

In comparison with wrought alloys, casting alloys contain larger proportions of alloying elements such as silicon and copper. This results in a largely hetero-

**Fig. 13** Automotive structures are likely to employ increasing amounts of 5754-O formed sheet for parts such as internal door stiffeners or (a) the entire body in white; (b) external body panels are more likely to be higher strength 6111-T4.

**Fig. 14** Power of extruded Al-Mg-Si alloys is the “put the metal where you need it” flexibility these alloys and the extrusion process provide.

geneous cast structure, i.e., one having a substantial volume of second phases. This second phase material warrants careful study since any coarse, sharp, and/or brittle constituent can create harmful internal notches and nucleate cracks when the component is later put under load. Fatigue performance is very sensitive to large heterogeneities, especially at or near the surface. As will be shown later, good metallurgical and foundry practice can largely prevent such defects.

The elongation and strength, especially in fatigue, of most cast products are relatively lower than those of wrought products. This is because current casting

**Fig. 15** Example of a premium forged aircraft part, usually of alloys such as 7050 or 7175-T74.

practice is as yet unable to reliably prevent casting defects. In recent years, however, innovations in casting processes such as squeeze casting have brought about some significant improvement in the consistency and level of properties of castings, and these should be taken into account in selecting casting processes for critical applications.

For applications where high ductility and toughness along with high strength, relatively high-purity versions of casting alloys like A356.0-T6 (rather than 356.0-T6) and A357.0-T6 (rather than 357.0-T6) are recommended.

**2xx.x: Al-Cu Alloys.** The major characteristics of the 2xx.x series are:

- Heat treatable; sand and permanent mold castings
- High strength at room and elevated temperatures; some high toughness alloys
- Approximate ultimate tensile strength range: 19–65 ksi

The strongest of the common casting alloys are heat-treated 201.0 and 204.0, which have found important application in the aerospace industry. Its castability is somewhat limited by a tendency to microporosity and hot tearing, so that it is best suited to investment casting. Its high toughness makes it particularly suitable for highly stressed components in machine tool construction, in electrical engineering (pressurized switchgear casings), and in aircraft construction.

Besides the standard aluminum casting alloys, there are special alloys for particular components, for instance, for engine piston heads, integral engine blocks, or bearings. For these applications the chosen alloy needs good wear resistance and a low friction coefficient, as well as adequate strength at elevated service temperatures. A good example is the alloy 203.0, which to date is the aluminum casting alloy with the highest strength at around 400°F (200°C).

**3xx.x: Al-Si + Cu or Mg Alloys.** The major characteristics of the 3xx.x series are:

- Heat treatable; sand, permanent mold, and die castings
- Excellent fluidity; high strength/some high-toughness alloys
- Approximate ultimate tensile strength range: 19–40 ksi
- Readily welded

The 3xx.x series of castings are one of the most widely used because of the flexibility provided by the high-silicon contents and its contribution to fluidity plus their response to heat treatment which provides a variety of high-strength options. As a result, they are the best choice for large and complex castings (Fig. 16). Further the 3xx.x series may be cast by a variety of techniques ranging from relatively simple sand or die casting to very intricate permanent mold, investment castings, and the newer thixocasting and squeeze casting technologies (Fig. 17).

Among the workhorse alloys are 319.0 and 356.0/A356.0 for sand and permanent mold casting, with A356.0-T6 for such critical applications as automotive wheels (Fig. 18). For die castings, 360.0, 380.0/A380.0, and 390.0 are the most widely used. The newer squeeze/forge cast technologies have generally employed A356.0-T6 and A357.0-T6.

Alloy 332.0 is also one of the most frequently used aluminum casting alloys because it can be made almost exclusively from recycled scrap.

**Fig. 16** Complex 3xx.x castings made by the investment casting processes provide the ability to obtain exceptionally intricate detail and fine quality.

**Fig. 17** Thixoformed A356.0-T6 and A357.0-T6 may be used for critical aircraft components.

**Fig. 18** Automotive wheels are often cast A356.0-T6.

**4xx.x: Al–Si Alloys.** The major characteristics of the 4xx.x series are:

- Nonheat treatable; sand, permanent mold, and die castings
- Excellent fluidity; good for intricate castings
- Approximate ultimate tensile strength range: 17–25 ksi

Alloy B413.0 is notable for its very good castability and excellent weldability, which are due to its eutectic composition and low melting point of 700°C. It combines moderate strength with high elongation before rupture and good corrosion resistance. The alloy is particularly suitable for intricate, thin-walled, leak-proof, fatigue-resistant castings.

These alloys have found applications in relatively complex cast parts for typewriter and computer housings and dental equipment, and also for fairly critical components in marine and architectural applications.

**5xx.x: Al–Mg Alloys.** The major characteristics of the 5xx.x series are:

- Nonheat treatable; sand, permanent mold, and die
- Tougher to cast; provides good finishing characteristics
- Excellent corrosion resistance, machinability, surface appearance
- Approximate ultimate tensile strength range: 17–25 ksi

The common feature of this group of alloys is good resistance to corrosion. Alloys 512.0 and 514.0 have medium strength and good elongation and are suitable for components exposed to seawater or to other similar corrosive environments. These alloys are often used for door and window fittings, which can be decoratively anodized to give a metallic finish or in a wide range of colors. Their castability is inferior to that of the Al–Si alloys because of its magnesium content and consequently long freezing range. For this reason it tends to be replaced by 355.0/AJSi5Mg, which has long been used for similar applications.

For die castings where decorative anodizing is particularly important, alloy 520.0 is quite suitable.

**7xx.x: Al–Zn Alloys.** The major characteristics of the 7xx.x series are:

- Heat treatable; sand and permanent mold cast (harder to cast)
- Excellent machinability and appearance
- Approximate ultimate tensile strength range: 30–55 ksi

Because of the increased difficulty in casting 7xx.x alloys, they tend to be used only where the excellent finishing characteristics and machinability are important. Representative application include furniture, garden tools, office machines, and farming and mining equipment

**8xx.x: Al–Sn Alloys.** The major characteristics of the 8xx.x series are:

- Heat treatable; sand and permanent mold castings (harder to cast)
- Excellent machinability

- Bearings and bushings of all types
- Approximate ultimate tensile strength range: 15–30 ksi

Like the 7xx.x alloys, 8xx.x alloys are relatively hard to cast and tend to be used only where their combination of superior surface finish and relative hardness are important. The prime example is for parts requiring extensive machining and for bushings and bearings.

## 4.2 Applications by Market Area

In the paragraphs that follow, a review will be made of the alloys often selected for products in a number of the major markets in which aluminum is used.

### Electrical Markets

The major products for which aluminum is used in electrical applications are electric cable and bus conductor, where the high electrical conductivity (60% IACS) makes aluminum a cost-effective replacement for copper products:

- Electrical conductor wire—1350 where no special strength requirements exist and 6201 where a combination of high strength and high conductivity are needed.
- Bus conductor—6101 (Fig. 2)
- Electrical cable towers—6063 or 6061 extruded shapes

### Building and Construction Markets

Building and construction encompasses those markets where architectural and/or structural requirements come together. Such applications include residential housing, commercial store fronts and structures, conference centers and areas (i.e., long roof bay requirements), highway bridges and roadside structures, and a variety of holding tanks and chemical structures (also considered under Petroleum and Chemical Industry Components). Among the choices:

- Bridges and other highway structures—6063 and 6061 extrusions (Figs. 8, 9); 5083, 5083, and 5454 plate (Fig. 9)
- Storefronts, curtain wall—6063 extrusions
- Building sheet; siding—3005, 3105; 5005 sheet
- Arena and convention center roofs—6061 extrusions with 5xxx alloy sheet panels (Fig. 8)
- Residential housing structures—6063 extrusions
- Architectural trim—5257, 5657, and 6463
- Composite wall panels—5xxx alloy sheet plus expanded polymers

### Automobile, Van, SUV, Bus, and Truck Applications

Automotive structures require a combination of aluminum castings, sheet and extrusions to cover all good opportunities to increase gasoline mileage and reduce pollutants. Among examples are the following:

- Frame—5182 or 5754 sheet (Fig. 13a) or, for space frame designs, 6063 or 6061 extrusions
- External body sheet panels where dent resistance is important—2008 and 6111 (Fig. 13b)
- Inner body panels—5083 and 5754
- Bumpers—7029 and 7129
- Air conditioner tubes, heat exchangers—3003 (Fig. 6)
- Auto trim—5257, 5657, and 5757
- Door beams, seat tracks, racks, rails, etc.—6061 or 6063
- Hood, decklids—2036, 6016, and 6111
- Truck beams—2014 and 6070 (Fig. 4)
- Truck trailer bodies—5454, 5083, and 5456 (Fig. 4)
- Wheels—A356.0 (Fig. 18), formed 5xxx sheet, or forged 2014-T6
- Housings, gear boxes—357.0 and A357.0 (Fig. 16)

### **Aircraft and Aerospace Applications**

Aircraft and aerospace applications require high strength combined with, depending upon the specific component, high fracture toughness, high corrosion resistance, and/or high modulus (sometimes all three). The result has been a great number of alloys and tempers developed specifically for this market, as illustrated by the examples below:

- Space mirror—high-purity aluminum
- Wing and fuselage skin—2024, alclad 2024, and 7050 plate or extrusions (Fig. 3)
- Wing structures—2024, 2124, 2314, and 7050 stiffened extrusions (Fig. 3)
- Bulkhead—2197, 7049, 7050, and 7175
- Rocket tankage—2195, 2219, and 2419 (Fig. 5)
- Engine components—2618
- Propellers—2025
- Rivets—2117, 6053
- If high modulus is critical—Li-bearing alloys 2090, 2091, 2195, or 8090
- If high fracture toughness is critical—2124, 2324, 7050, 7175, and 7475
- For maximum fracture toughness—7475
- If stress-corrosion resistance is important—7X50 or 7X75 in the T73-type temper
- If resistance to exfoliation attack is vital—7xxx alloys in the T76-type temper
- For welded construction, as for shuttle tanks—5456, 2219, and 2195

### **Marine Transportation**

Many aluminum alloys readily withstand the corrosive attack of marine salt-water, and so find applications in boats, ships, offshore stations, and other components that are immersed in saltwater:

- Hull material—5083, 5383, 6063 and 6061 (Fig. 11)
- Superstructure—5083 and 5456
- Structural beams—5083, 5383, 6063, and 6061 (Fig. 11)
- Off-shore stations, tanks—5083 and 5456 (Fig. 12)

### **Rail Transportation**

Much as for auto and truck bodies, aluminum lends itself to railcar structural and exterior panel applications:

- Beams—2014, 6061, and 6070
- Exterior panels—5456 and 6111
- Tank cars—5454 and 5083
- Coal cars—5454, 5083, and 5456 (Fig. 10)
- Cars for hot cargo—5454

### **Packaging Applications**

Packaging applications require either great ductility and corrosion resistance for foil and wrapping applications or great strength and workability for rigid container sheet applications, i.e., cans. Alloy choices include:

- Aluminum foil for foods—1175 (Fig. 1)
- Rigid container (can) bodies—3004 (Fig. 7)
- Rigid container (can) ends—5182

### **Petroleum and Chemical Industry Components**

The excellent combination of high strength combined with superior corrosion resistance plus weldability makes a number of aluminum alloys ideal for chemical industry applications, even some involving very corrosive fluids:

- Chemical piping—1060, 5254, and 6063
- Pressure vessels (ASME code)—5083, 5086, 6061, and 6063
- Pipelines—6061, 6063, and 6070
- Cryogenic tankage—5052, 5083, 5454, 6063, and 6061
- Containers for hydrogen peroxide—5254 and 5652

### **Other Markets**

While not major markets in themselves, a variety of specialty products find great advantage in aluminum alloys:

- Screw machine products—2011 and 6262
- Appliances—5005 and 5052
- Tread plate—6061
- Weld wire—4043 (for welding 6xxx alloys), 5356, 5183, and 5556 (for welding 5xxx alloys)

### 1 INTRODUCTION

Copper and copper alloys comprise one of the broadest and most versatile groups of engineering materials. Almost 500 copper alloys are currently recognized in the United States, and hundreds more are classified under international standards. Copper alloys are also produced in all common product forms, further expanding the possible choices.

The large selection may seem daunting, but choosing the correct alloy is simplified by the fact that copper metals are normally chosen for particular physical or mechanical properties, and alloys with the desired properties can easily be sorted out. A need for very high electrical or thermal conductivity, for example, generally points to one of the coppers or high-copper alloys, while superior machinability suggests that a leaded alloy ought to be considered. There are likewise alloys that are selected primarily for their superior corrosion resistance, formability, castability, mechanical properties, biofouling resistance, and biostatic behavior, among other things.

On the other hand, the main reason copper and its alloys are so widely used is that they offer a better *combination* of useful properties than can be found in

other materials. This fortunate circumstance reduces the level of compromise needed to satisfy all design requirements satisfactorily.

The designer's first choice, however, is usually that of a suitable product form: wire or rod; sheet, strip, or plate; castings; and so forth, and for that reason, alloys listed in this chapter are grouped according to the forms in which those alloys are customarily produced. Data is presented for a broad and representative selection of alloys. Unfortunately, space constraints prohibit inclusion of data for all currently registered alloys in all product forms and in all tempers. Comprehensive information on all alloys is available on line at *The Copper Page* (<http://www.copper.org>), through the Copper Data Center (<http://www.csa.com/copperdata/>), and from the Copper Development Association (CDA).

## 2 STRUCTURE OF THE COPPER INDUSTRY

Copper is truly a global metal, found in economic quantities in all continents except Antarctica. Chile currently leads the world in copper production, having passed the United States (which retains second place) in the early 1990s. Other major copper-producing countries include Peru, Canada, Mexico, Poland, Zaire, Zambia, Australia, Philippines, Indonesia, Papua New Guinea, and the Commonwealth of Independent States (CIS; former Soviet Union). The (former) U.S. Bureau of Mines estimates that worldwide land-based copper resources stand at 1.6 billion metric tons (mt), with an additional 1.8 billion mt contained in deep-sea nodules. Global copper depletion, once forecast as a looming threat, is now seen as an unfounded concern.

Not all countries that mine substantial quantities of copper actually produce commercial metal. Copper concentrates and an impure form of metal known as blister copper are traded worldwide to countries having the smelters and refineries needed to complete the metal production process. Western Europe and Japan, for example, mine little copper but produce significant amounts for their own use and for export.

Copper is a commodity metal, and the Comex and the London Metal Exchange fix published prices. The exchanges account for only a fraction of the copper actually traded worldwide, however, and the bulk of trading takes place between producers and users.

Major U.S. copper-mining states include Arizona, Utah, and Nevada plus, to a lesser extent, New Mexico. Large deposits in the Upper Peninsula of Michigan, once the primary source of domestic copper, have largely been mined out. The U.S. copper-mining industry has consolidated considerably in recent years and only three domestic producers—Phelps Dodge, Asarco Grupo Mexico, and Kennecott Utah Copper—can be considered major players in the sense that they operate large mines on U.S. soil. On the other hand, these companies and others have extensive holdings in copper-producing regions elsewhere in the world, and, conversely, a number of foreign companies either have interests in, or wholly own U.S.-based copper producers, including two of those named above.

Copper smelters, which produce blister copper from concentrates, are generally located near mines. Refineries, where blister is purified to 99.9+% pure cathode copper through an electrolytic process, are somewhat more widespread, although most are also found in the copper-mining states. Several large refineries are located in Texas.

Copper products are produced by fabricators: wire mills, brass mills, foundries, and metal powder plants. Their plants are found throughout the country. The U.S. copper industry was once very much vertically integrated, but it has become increasingly diversified and few fabricators now retain formal ties to producers.

As explained below, copper wire and cable and other electrical products are usually made from newly mined and refined copper. Copper tube and alloy products are made from a combination of refined and scrap copper, as well as copper alloy scrap. Copper is, in fact, among the most thoroughly recycled industrial metals.

### 3 COPPER ALLOY DESIGNATIONS

In the United States and several other countries, copper and copper alloys are classified under the Unified Numbering System for Metals and Alloys (UNS), a system managed jointly by the American Society for Testing and Materials (ASTM) and the Society of Automotive Engineers (SAE). CDA is responsible for assigning numbers to copper alloys, which are identified by a five-digit code preceded by the letter “C.” The codes are extensions of a previous and once widely used three-digit numbering system, which was also administered by CDA. Thus, for example, the alloy formerly known as copper alloy 360 by its three-digit “CDA number” is now designated UNS C36000. It should be noted that the UNS numbers are not specifications; they are merely standard designations for defined compositions.

Copper alloys are sometimes also referred to by descriptive historical names such as “free-cutting brass” and “naval brass.” Colorful as such names may be, they can be ambiguous, and it is strongly recommended that alloys be called out by their UNS numbers.

In addition to its UNS number, specification of a copper or copper alloy usually requires inclusion of a *temper designation*. Temper is a term that identifies the metallurgical state of an alloy as well as the mechanical and physical properties resulting from its processing history. Terms such as annealed, half-hard, and precipitation heat treated, along with their coded abbreviations, are listed in Tables 1 and 2 for wrought and cast alloys, respectively. The tables are taken from ASTM B601. Mechanical property data tables in this chapter include the most commonly specified tempers for the alloys listed. Data corresponding to tempers not listed here may be found at <http://properties.copper.org/> and in publications available from CDA.

**Copper Alloy Families.** The copper metals are conventionally grouped into several families according to similarities in composition, and hence, properties. UNS numbers from C10100 through C79999 denote wrought (i.e., drawn, rolled, extruded, or forged) alloys. Cast alloys are numbered from C80100 through C99999.

The family identified as *coppers* include metals that have a designated minimum copper content of 99.3% or higher. Wrought coppers (wire, rolled products, extrusions, etc.) include UNS designations ranging from C10100 through C15999, although all numbers are not in use. Cast coppers are numbered from

**Table 2 Temper Designations for Coppers Casting Alloys**  
(Based on ASTM B601)

| Temper Designations                                            | Temper Names                           |
|----------------------------------------------------------------|----------------------------------------|
| <i>Annealed—O</i>                                              |                                        |
| O10                                                            | Cast and annealed (homogenized)        |
| O11                                                            | As-cast and precipitation heat treated |
| <i>As-Manufactured—M</i>                                       |                                        |
| M01                                                            | As sand cast                           |
| M02                                                            | As centrifugal cast                    |
| M03                                                            | As plaster cast                        |
| M04                                                            | As pressure die cast                   |
| M05                                                            | As permanent mold cast                 |
| M06                                                            | As investment cast                     |
| M07                                                            | As continuous cast                     |
| <i>Heat-Treated—TQ</i>                                         |                                        |
| TQ00                                                           | Quench hardened                        |
| TQ30                                                           | Quench hardened and tempered           |
| TQ50                                                           | Quench hardened and temper annealed    |
| <i>Solution Heat Treated and Spinodal Heat Treated—TX</i>      |                                        |
| TX00                                                           | Spinodal hardened (AT)                 |
| <i>Solution Heat Treated—TB</i>                                |                                        |
| TB00                                                           | Solution heat treated (A)              |
| <i>Solution Heat Treated and Precipitation Heat Treated—TF</i> |                                        |
| TF00                                                           | Precipitation hardened (AT)            |

C80100 through C81399. These metals comprise various grades of commercially pure copper that are used primarily for electrical and electronic products.

*High-copper alloys* include those wrought grades with designated copper contents less than 99.3% but higher than 96.0% (UNS C16200 through C19999), which do not fall into any other copper alloy group. Cast high-copper alloys (C81300 through C82800) have minimum copper contents in excess of 94.0% and may contain silver for special purposes. Wrought or cast, these alloys combine electrical and thermal conductivities approaching those of pure copper but with higher strength, hardness, and wear resistance. Corrosion resistance may be higher or lower than that exhibited by the pure metal, depending on interactions between the environment and specific alloys. Common uses for high-copper alloys include electrical connectors, resistance welding electrodes, slip rings, coax cable shields, and trolley wire.

*Brasses* are alloys containing zinc as the principal alloying element with or without secondary alloying elements such as iron, aluminum, nickel, and silicon. The wrought brasses comprise three subfamilies:

- Copper–zinc alloys (ordinary brasses), C21000 through C28999
- Copper–zinc–lead alloys (lead brasses), C30000 through C39999
- Copper–zinc–tin alloys (tin brasses), C40000 through C9999

Cast brasses are grouped into four subfamilies:

- Copper–tin–zinc alloys (including semired brasses and leaded red brasses, C83300 through C83999, semired and leaded semired brasses, C84000 through C84999, and yellow and leaded yellow brasses, C85000 through C85999)
- So-called manganese bronze alloys (also known as high-strength yellow brasses) and their leaded variants, C86000 through C86999
- Copper–zinc–silicon alloys (silicon brasses and “bronzes”), C87000 through C87999

This large group of alloys offers a wide range of useful properties, which vary widely according to composition, product form, and temper. Conductivity, while substantially lower than copper or high-copper alloys, is often adequate for electrical applications such as connectors. Various brasses, again depending on composition, exhibit superior formability, machinability, and/or castability, as well as good corrosion resistance and moderate to high mechanical properties. Among the economical yellow brasses are wrought grades with excellent hot forging properties and cast varieties that are well suited for the cost-effective permanent mold (gravity die) casting process, described below. Applications for wrought brasses include springs, contacts, connectors, welding wire, jewelry, munitions, tube sheets, marine hardware, architectural cladding, and a countless assortment of stamped, rolled, forged, and machined products. With their favorable combination of strength, corrosion resistance, attractive color, and the ability to take a smooth finish, cast brasses are most commonly used in plumbing fixtures and fittings, but they are also widely used for decorative and architectural products, as well as pumps, valves, and propellers and other marine hardware, to name just a few examples. Further information about brasses can be found in the applications areas on <http://www.copper.org>.

*Bronzes*, broadly speaking, are copper alloys in which the major alloying element is neither zinc nor nickel. Originally, “bronze” described alloys with tin as the only or principal alloying element. Today, the term is generally used not by itself but with a modifying adjective to describe the main added element. There are four families of wrought bronzes:

- Copper–tin–phosphorus alloys (phosphor bronzes), C50100 through C52400
- Copper–tin–lead–phosphorus alloys (leaded phosphor bronzes), C53200 through C55284
- Copper–aluminum alloys (aluminum bronzes), C60600 through C64400
- Copper–silicon alloys (silicon bronzes), C64700 through C66100

There are also four families of cast bronzes:

- Copper–tin alloys (tin bronzes), C90200 through C91700
- Copper–tin–lead alloys (leaded and high-leaded tin bronzes), C92200 through C92900 and C93100 through C94500, respectively

- Copper–tin–nickel alloys (nickel–tin bronzes), C94700 through C94900
- Copper–aluminum–iron and copper–aluminum–iron–nickel alloys (aluminum bronzes), C95200 through C95810

Wrought bronzes, in sheet and strip form, are used for electrical springs and connectors. Leaded versions are used for a broad variety of machined components requiring high strength and good corrosion resistance. Wrought silicon and aluminum bronzes, for example, are used for bolts, shafts, and other industrial products. Cast bronzes are used for pump, valve and fitting components, wear rings, gears, and products for the chemical, mining, petrochemical, and electroplating industries. Many cast bronzes are used in sleeve bearings, which are discussed later in this chapter. Because of their good castability and favorable weathering characteristics, cast bronzes are the metals most often used in statuary and plaques. Several useful articles dealing with bronzes can be found at <http://www.copper.org/industrial/homepage.htm>.

*Copper–Nickels* are copper alloys in which nickel is the principal alloying element. Iron, manganese, niobium (columbium), and other elements may also be present. Both wrought (C70100 through C72900) and cast (C96200 through C96800) copper–nickels exhibit outstanding corrosion and stress–corrosion cracking resistance, especially in seawater. Biofouling resistance (the ability of an alloy to inhibit the attachment of marine organisms) ranges from moderate to excellent, generally increasing with copper content. Copper–nickels are used for condenser and heat exchanger tubes, seawater piping systems, pumps, valves, and fittings. Copper–nickel sheet, applied as cladding or sheathing to seagoing vessels and offshore platform legs, significantly reduces drag caused by the buildup of algae and other marine life. A number of informative studies describing the properties, uses, and fabrication of copper–nickels are available at <http://marine.copper.org/>.

*Nickel–silvers* are copper–nickel–zinc alloys or nickel brasses. Nickel gives them the color for which they are named. They offer the good corrosion resistance and favorable mechanical properties inherent to brasses. Wrought nickel–silvers (C73200 through C79900) are available in sheet and strip as well as rod and bar forms. Some alloys produced as rod contain lead for improved machinability. Uses include electrical and electronic connectors, decorative hardware, jewelry, tableware, eyeglass frames, and musical instrument components. Cast nickel–silvers (C97300 through C97800) have long been used in valves and fittings for food and beverage handling equipment.

*Leaded coppers* are metal–matrix composites (MMCs) rather than true alloys in that lead is not miscible in copper to any appreciable extent. Available only in cast versions (C98200 through C98640), these materials are used exclusively for special-duty bearings.

Finally, there are a number of *miscellaneous copper–zinc alloys* in wrought forms and *special alloys* for cast products whose compositions preclude their inclusion among other alloy families. Wrought alloys (C66400 through C66900) include alloys supplied as sheet and strip, wire, tubular products, and extruded rod and bar for applications such as springs, switch components, condenser tube, valve stems, gears, wear plates, piston rings, propeller shafts, and pole-line hard-

ware. Cast special alloys (C99300 through C99750) include materials designed to provide such unconventional physical or mechanical properties as high damping capacity, ferromagnetic permeability and shape-memory effects.

#### 4 PRODUCT FORMS

Copper and copper alloys are produced in all product forms, although some may be available in several forms while others are only produced in one or two. Basic compositions are often modified to make alloys amenable to manufacture in a particular form, a practice that is sometimes reflected in the final two digits of the UNS numbering codes.

#### 5 ELECTRICAL AND ELECTRONIC WIRE PRODUCTS

Copper's largest single use, exceeding 60% of consumption in many countries, is for electrical applications, and wire and cable products make up the bulk of this market. In the United States, about 45% of all refined copper comes to market as wire and cable, the remaining "electrical" copper being used in other-than-wire products such as busbars, switchgear, pole-line hardware, and tubular windings in large gas-cooled electric generators.

There is little materials selection involved in electrical wire, since virtually all of it is made from electrolytic tough pitch (ETP) copper, C11000. It contains a minimum of 99.90% Cu, making it one of the purest metals in commercial use. Purity largely determines copper's electrical and thermal conductivity, and even minute quantities of most impurity elements severely degrade these properties.

Copper wire products are identified by their end uses. *Building wire*, which includes both insulated and uninsulated wire within buildings and structures, accounts for the largest fraction of copper wire used; *magnet wire* is an insulated or enameled product used in electric motors, transformers, relays, and similar products; *telecommunications cable* includes both voice and data cable; *power cable* is that used by utilities and for heavy industrial conductors; while *automotive wire* is used in wiring harnesses and other purposes. There are also several miscellaneous wire types including apparatus wire, cord sets, electronic wire and cable [local area network (LAN) cable], control and signal wire and cable, and bare wire, among others. Organizations such as the National Electrical Manufacturers Association (NEMA), the Institute of Electrical and Electronic Engineers (IEEE), the National Fire Protection Association (NFPA), and others generally establish specifications for the production and use of electrical wire products.

The conductivity of copper is expressed in units of a percentage of the International Annealed Copper Standard (IACS). This standard is based on an annealed copper wire having a density of 8.89 g/cm<sup>3</sup>, 1 m long, weighing 1 g, with a resistance of 0.15328  $\Omega$ . This standard was assigned the value 100 at 20°C (68°F). It is not uncommon for commercially pure copper products to have IACS conductivity values greater than 100% because of improved processing techniques that have been developed since the adoption of the standard in 1913.

For example, C11000 exhibits a conductivity 101% IACS. The so-called *oxygen-free* or *OF coppers*, notably C10100 (oxygen-free, electronic) and C10200—there are others—offer slightly higher conductivity, but this is rarely

required. Instead, OF coppers are selected for their combination of high conductivity and good weldability. Dissolved oxygen found in ETP and some other coppers causes welding problems. The oxygen contents of OF coppers are low enough to avoid such problems. The addition of deoxidizers such as phosphorus and boron also helps by tying up oxygen in harmless compounds, but deoxidizers—especially phosphorus—also reduce conductivity. Table 3 contains conductivity data, as well as other physical properties, for coppers and selected copper alloys. A listing of physical and mechanical properties for all current UNS copper metals is available on line at <http://properties.copper.org/servlet/com.copper.servlet.CDAPropertiesSelectionServlet>.

Coppers containing traces of tellurium, cadmium, silver, chromium, zirconium, and titanium, alone or in combination, offer slightly higher mechanical properties. Purity is high enough to classify the metals as coppers rather than high copper alloys. This is reflected in their conductivities, which are typically higher than 90% IACS. Tellurium-bearing copper (C14500) and zirconium copper (C15000) are examples of such coppers. Understanding their uses requires a quick explanation of strengthening in copper.

Coppers are strengthened almost exclusively by cold working, as in wire drawing. The effects of cold work are removed by annealing, i.e., heating the copper above a particular temperature, either intentionally or as a result of high current flow in service. Some secondary elements raise the temperature at which copper begins to soften or anneal. Softening resistance can be important in, for example, pin-type electrical connectors, which are made from these coppers, as well as from high-copper alloys, brasses, bronzes, and other alloys.

A large body of technical data and literature about copper's electrical and electronic applications can be found in the Electrical Energy Efficiency, Power Quality and Telecommunications areas of *The Copper Page*, <http://www.copper.org>.

## 6 SHEET, STRIP, AND PLATE PRODUCTS

In contrast to wire products, which are made from a relatively small number of coppers, products produced as sheet, strip, and plate are available in a large selection of coppers and (especially) copper alloys. The uses to which these metals are put can broadly be grouped into architectural and decorative applications, electrical/electronic technologies, and industrial products.

### 6.1 Architecture

Copper has a long history of use for roofing, flashing and gutters, and other architectural products. In the United States, such products were until recently found mainly on public buildings. Today, use is growing in domestic housing, and copper metals are being selected for new applications such as wall and column cladding.

One reason for copper's growth is that the patinas that form naturally on exposed surfaces over time can now be applied during manufacture, thus providing the architect/designer with an even larger palette of colors and finishes. Information about copper's architectural uses can be accessed at <http://architecture.copper.org/>.

## 6.2 Electrical and Electronic Alloys

Electrical and electronic connectors, contacts, leadframes and components of switches, relays, and similar products form another important use of copper metals. The principal property of concern here is electrical conductivity, followed by formability, corrosion resistance, and spring properties, i.e., the ability to maintain required contact forces. (Thermal conductivity roughly parallels electrical conductivity, and like electrical conductivity, it decreases with increasing concentrations of alloying elements.) The ability to retain mechanical properties at moderately elevated temperatures is also important. This property, known as stress-relaxation resistance, is important in high-current-carrying components, components that require constant contact forces over time and products that are subjected to high “burn-in” currents during testing. Mechanical properties of sheet, strip, and plate alloys, including those used in electrical and electronic applications, are listed in Table 4.

The copper alloy most commonly used in electrical connectors is cartridge brass, UNS C26000. The alloy’s electrical conductivity is only 28% that of pure copper, but that is sufficient for many applications. C26000 is also the most formable of the brasses, and its ductility enables complex connectors to be produced at high speed. Brasses containing less than the 30% zinc found in C26000 have higher conductivity, but they are somewhat weaker and less formable. No practical benefit is gained by adding more than 30% zinc to brass for electrical connectors.

Phosphor bronzes comprise the next-most popular group of connector alloys. The phosphor bronzes trade-off conductivity for higher strength and are used to provide high contact forces when electrical conductivity is not a prime concern. Conversely, they can provide equivalent contact force with less metal. With innovative design, reducing the weight of material required for each contact can often offset the cost penalty for alloys carrying a higher price per pound.

Unlike the brasses, which offer a wide range of electrical conductivity (28–56% IACS), conductivities of phosphor bronzes range from only 11 up to 20% IACS, although there are exceptions. Conductivity of phosphor bronze A (5% tin, UNS C51000), the leading alloy, is 15% IACS, only about one-half that of C26000, but it is twice as strong.

Phosphor bronze C (C52100) is another popular alloy in this family. With 8% tin and a small amount of phosphorus, it is stronger but not so highly conducting as C51000. Alloy UNS C51100 offers somewhat higher conductivity than C51000 and C52100 and is also frequently used. These alloys are available in strip form in a variety of tempers. See the data tables for conductivity and mechanical properties.

Coppers containing small quantities of tellurium, zirconium, magnesium, cadmium (now in disfavor due to its adverse effects on the environment), chromium, and iron, in some cases in combination with phosphorus, can provide conductivity of around 80–90% IACS with yield strengths between about 35 and 70 ksi (240 and 480 MPa).

High-copper alloys offer combinations of high conductivity and high mechanical properties. Typical alloys in this class include chromium–coppers such as C18200 and C18400; copper–iron–phosphorus alloys (C19210, C19400, and

Table 4 Mechanical Properties of Selected Sheet and Strip Alloys (Copper Development Association, Inc.)

\* Fatigue strength:  $100 \times 10^6$  cycles unless indicated as  $[N] \times 10^6$ .

others), and copper–iron–tin–zinc–magnesium alloys (C19800). In the hardened condition, the alloys exhibit yield strengths between about 50 and 70 ksi (345 and 483 MPa) and conductivities between 60 and 80% IACS.

There are a number of alloys in the conductivity range from 25 to 50% IACS, including certain beryllium coppers, brasses, tin brasses, phosphor bronzes, and copper–silicon alloys. “Red” or high-conductivity beryllium coppers such as C17410 and C17510 are at the top of this class, with yield strengths between 60 and 110 ksi (414 and 758 MPa) and conductivities in the 45–48% range.

Finally, there is a group of alloys that provides very high strength with somewhat limited electrical conductivity, typically in the range from less than 10 to nearly 25% IACS. These compositions include the high strength or “gold” beryllium coppers (C17200 and others) and copper–nickel–tin alloys such as C72600, which can be strengthened by precipitation hardening or by complex metallurgical reactions such as spinodal decomposition.

Connector alloys are an especially fertile field for copper alloy development, and new compositions offering combinations of electrical and mechanical properties tailored for specific applications are continually being brought to market. Descriptions of such alloys, as well as extensive information about the selection of other copper alloys for electrical and electronic connectors can be found at <http://connector.org>. Information regarding proprietary alloys offered by U.S. manufacturers is available at web sites such as:

### 6.3 Industrial Products

A number of coppers and copper alloys are produced in plate form for a variety of industrial applications. Copper plate is widely used for busbars. UNS C11000 is normally specified, but one of the OF coppers should be selected if welding is necessary.

Various brasses are also produced as plate, often for industrial and marine products where high corrosion resistance is needed. Muntz metal (C28000), admiralty (UNS C44300–C44500), and naval brasses (UNS C46200–C48600) are copper–zinc brasses modified by the addition of tin and/or nickel (for higher strength and improved corrosion resistance), as well as elements such as arsenic and antimony that inhibit the occurrence of a particular form of aqueous corrosion known as dezincification. Lead may be added to improve machinability.

Manganese and silicon bronzes are used in plate form where higher strength, high wear resistance, and better corrosion resistance than that found in brasses is needed. Aluminum bronzes comprise an interesting group of complex alloys, whose properties, depending on composition, range from moderate to very high strength. In addition to aluminum, these alloys usually contain combinations of iron, niobium (columbium), nickel, and manganese. Examples include UNS C61400 and C63200.

Mechanical properties of alloys produced in rod, bar, shapes, and mechanical wire are listed in Table 5. Properties of alloys generally produced in sheet, strip, and plate forms are listed in Table 4. Numerous alloys are listed in both tables; properties may vary with product form.

## 7 TUBULAR PRODUCTS

Plumbing products, including water tube and fittings plus various other products broadly classified as commercial tube and fittings, constitute copper's second largest end use. In the United States, copper continues to account for approximately 80% of plumbing installations, largely based on its proven reliability. Interestingly, U.S. copper plumbing tube manufacturers now offer a 50-year warranty on the product. Mechanical property data for alloys produced in tube form are listed in Table 6.

### 7.1 Water Tube

Plumbing tube manufactured in the United States is made from phosphorus deoxidized, high residual phosphorus (DHP) copper, UNS C12200. Copper plumbing tube is in fact made to very stringent compositional limits under which as many as a dozen or more trace elements are strictly controlled. The level of care exercised is quite remarkable in that roughly two thirds of domestic plumbing tube is made from scrap copper that has been recycled, remelted, and re-refined.

A group of products commonly referred to as commodity tube includes water tube, drainage tube, medical gas tube, and tube for air-conditioning and refrigeration (ACR) field service. Water tube, the most common of the plumbing tubes produced, refers to types K (heaviest), L (standard), and M (lightest) wall thickness schedules of ASTM B88, Specification for Seamless Copper Water Tube. Of identical composition as water tube are drainage tube, type DWV of B306, Specification for Copper Drainage Tube (DWV), and medical gas tube, types K and L (the same wall thickness as the corresponding water tube of the same types) of ASTM B819, Specification for Seamless Copper Tube for Medical Gas Systems, which are produced for specific applications. The thinner wall of DWV tube makes it more economical for use in low-pressure drainage systems, and the internal cleanliness of medical gas tube is required for systems conveying oxygen, nitrogen, nitrous oxide, medical compressed air, or other gases used in patient care, and even oxygen for other applications. Internally cleaned tube similar to medical gas tube is the commodity tube for use in connecting air-conditioning and refrigeration system equipment, produced to ASTM B280 as type ACR. With the exception of ACR tube that is sized by outside diameter, the actual outside diameter of these commodity tubes is  $\frac{1}{8}$  in. (3.2 mm) larger than the nominal or standard size. Depending on the application, plumbing tube

Table 5 Mechanical Properties of Selected Rod, Bar and Mechanical Wire Alloys (Copper Development Association, Inc.)

is available in the annealed state (generally in coils) and in drawn tempers (straight lengths).

## 7.2 Commercial Tube and Fittings

Commercial tube is primarily used in air-conditioning and refrigeration systems. The tube is chemically similar to plumbing tube; however, dimensions are based on outside diameters, and some tubes are produced with enhanced inside and outside profiles for better heat transfer.

Other applications for copper tube include condenser, evaporator, and heat exchanger tubes; gas, heater, and oil burner lines; fire sprinkler systems; plumbing pipe and steam tubes; brewery and distillery tubes; gasoline, hydraulic, and oil lines, and rotating bands. A new designation, type G, refers to tube for fuel gas [both natural and liquid propane (LP) gas] distribution systems, a relatively new but rapidly growing application.

## 7.3 Alloy Tube

Copper–iron (UNS C19200), and in recent years, copper–nickel (UNS C70600) is specified for automotive hydraulic brake lines. The copper–nickel is especially resistant to stress–corrosion cracking and to attack by road salts.

Selection of alloys for condenser and heat exchanger tube is based on heat transfer rate (conductivity), corrosion resistance, and resistance to cavitation and biofouling. In general, conductivity is highest in pure copper and high-copper alloys, whereas mechanical and chemical properties are highest in more highly alloyed grades. Corrosion resistance of alloys cannot be ranked quantitatively since performance depends strongly on specific exposure conditions; however, resistance also generally increases with the degree of alloying.

Thus, the designer's choice ranges from simple brasses such as UNS C23000, tin brasses such as UNS C43500, UNS C44300, and UNS C68700 (arsenical aluminum brass), through silicon bronzes C65100 and C65500, aluminum bronzes such as UNS C60800, and finally copper–nickels UNS C70600 and C71500. Alloy C70600 is widely used for seacoast power plant condensers and critical piping systems on offshore platforms. The alloy's high biofouling resistance keeps piping systems free from marine growth. Alloy C71500, with 30% nickel, is used in severe-duty marine condensers and saltwater systems, as well as desalination equipment. Further information on copper tube, pipe and fittings, and on the selection of copper alloys and other commercial tube products can be found at <http://piping.copper.org/> and <http://www.copper.org/mechanical/homepage.htm>, respectively.

## 8 ROD, BAR, AND MECHANICAL WIRE

Copper metals used in products manufactured by machining, hot forging, and cold heading are supplied as extruded and/or drawn rods, bars, and mechanical wire. When referring to copper products, *rod* means round, hexagonal, or octagonal forms supplied in straight lengths, i.e., not coiled. *Bar* products have square or rectangular cross sections and are also sold in straight lengths. *Shapes* are straight lengths with oval, half-round, geometric, or custom-ordered cross sections, and *wire* can have any cross section and is supplied in coils or on spools.

Products are specified by grade and temper. Temper definitions for wrought products are listed in Table 1. Mechanical properties corresponding to the most commonly selected tempers are listed in Table 5. The data are identical to values published in the *Society of Automotive Engineers (SAE) Handbook, Vol. 1, Materials*, Warrendale, PA (published annually).

## 8.1 Machined Products

By far, the alloy most often selected for machined products is UNS C36000, free-cutting brass. The alloy, a yellow brass containing a few percent of lead, is so readily machinable that it is accepted as the standard against which the machinability ratings of other metals are compared. Evaluations conducted in accordance with an established ASTM test method show that in the half-hard temper (H02), C36000 can theoretically be machined five times faster than SAE 12L14 free-machining steel at equivalent tool wear rates. Few automatic screw machines or machining centers can operate at such speeds, but the superior machinability of C36000 is also an important economic factor at conventional cutting rates. As a general rule of thumb, products in which more than about 55% of the starting rod is removed by machining—as is usually the case—will be less costly when made from C36000 compared with identical products made from 12L14.

When machined, free-cutting brass produces what are known as type I chips, small fragments that are easily removed from the cutting area. The chips form as a result of the alloy's lead content, which also acts as an internal lubricant and coolant. Other leaded copper alloys share this property to varying degrees. Type I alloys exhibit machinability ratings ranging from 100 (highest, for C36000) to 50. Type II chips are short, curly or serrated depending on alloy and the type of machining operation employed. Alloys displaying this form of chip have machinability ratings ranging from 60 to 20. While not quite as machinable as type I alloys, these grades offer higher mechanical properties and enhanced corrosion resistance, among other attributes. Alloys that form type III chips, which are long and tangled, are less well suited to high-speed automatic machining operations, and they are generally selected for other reasons. Machinability ratings range from 40 to 20, indicating that they can certainly be machined, only not at the high speeds available with leaded alloys. Therefore, when cost is a primary design consideration and production quantities are large enough to warrant the use of automatic screw machines or numerically controlled machining centers, free-cutting brass is normally the best starting point. When higher mechanical properties, specific corrosion resistance, or other special properties are needed, other copper alloys can be considered.

Brass chips are always recycled, and the sale of these chips partly offsets the metal's higher initial cost. Steel chips are difficult to recycle and have almost no value. Further savings are realized by the fact that brass products usually do not require plating or synthetic coatings for corrosion protection. Protective coatings add considerable cost and can give rise to environmental concerns, but brass's inherent corrosion resistance makes them unnecessary.

The yield strength of C36000 in the half-hard temper is 43 ksi (310 MPa). This value is somewhat lower than the strength of 12L14, but it is adequate for most screw-machined products. While the lead present in C36000 gives the metal

its high machinability, it does restrict ductility somewhat. Products with severe knurling or thread-rolling in addition to machining can be specified in brasses such as C34500 and C35300, which contain less lead but have machinability ratings that are nearly as high as that of C36000.

Free-cutting brass (and other alloys) is also produced in custom-designed extruded shapes. Use of such shapes can cut machining time and reduce the number of components in an assembly. Custom extrusion dies are inexpensive and can normally be ready for use within a few days. A series of informative articles describing the properties and benefits of using free-cutting brass can be found at <http://brassbar.copper.org/alloy360/homepage.ihtml>. Additional literature on the material is available from CDA in print and on CD-ROM.

## 8.2 Forgings

Forging, or hot stamping, yields products with high, uniform mechanical properties and fine surface finishes. The process is often selected for products such as pump impellers, decorative architectural hardware and valves, and other pressure-retaining products where integrity is important. Because the forging process yields products with near net shapes, it competes with casting—especially permanent-mold and die casting—when large production runs are planned. Design limitations associated with forgings include avoidance of re-entrant angles and very thin sections and provision of relief angles of about 5° on axially oriented surfaces. On the other hand, forgings' dense structure, internal cleanliness, and consistent dimensions enable components to be designed with thinner walls than castings having equivalent pressure ratings. Most copper-base forgings are modest in size, although the process known as ring forging is capable of producing circular products as large as 25 ft (76 m) in diameter.

Many copper alloys, including brasses, nickel silvers, aluminum and silicon bronzes, copper–nickels, high-copper alloys, and copper itself are routinely forged. Forging brass, UNS C37700, is particularly well adapted to the process, offering die life up to 50,000 parts. It is a yellow brass, similar to free-cutting brass but containing only about one-half as much lead. The alloy shares many of C36000's properties, including good machinability (rating = 80) and corrosion resistance. Like other brasses, it can be polished to a high luster and readily accepts electroplating. Further information about copper-base forging alloys can be found at <http://brassbar.copper.org/forgings.htm>. Mechanical properties of forged copper alloys are listed along with rod, bar, and mechanical wire alloys in Table 5.

## 8.3 Mechanical Wire

Pure copper and single-phase copper alloys such as low-zinc brasses, copper–nickels, and high-copper alloys have exceptional ductility at low temperatures. This makes them good candidates for cost-effective forming processes such as cold heading. Countless screws, rivets, electrical connector pins, jewelry items, shafts, actuating arms, and high-strength, corrosion-resistant bolts are produced by way of such processes.

Cold working increases the strength and hardness of these alloys, adding to whatever other strengthening mechanisms may be present in the alloy (see Table 5). Cold working does not seriously inhibit an alloy's useful properties, although

ductility obviously decreases, and susceptibility to stress corrosion cracking may increase in susceptible alloys and aggressive environments due to the presence of residual stresses. Electrical conductivity of cold-worked alloys will be slightly lower than that seen in annealed materials.

## 9 CASTINGS

Cast copper alloys are among the oldest fabricated materials. Ancient artisans only had copper and crude tin bronzes to work with, but today's designers continue to find new uses for cast copper alloys of all types. Cast copper alloys are specified for their favorable mechanical properties, good friction and wear properties, high conductivity, excellent machinability and fabricability, biofouling resistance, low manufactured cost, and attractive appearance. Mechanical property data for cast copper alloys are listed in Table 7.

Casting is often chosen over other manufacturing methods because it offers low cost. Copper alloys are not the lowest-cost raw materials, but they compete successfully with other cast metals—especially stainless steels and nickel-base alloys—because their predictable castability increases foundry yields, reducing rejection rates and keeping overall foundry costs low. The alloys' high machinability reduces the cost of secondary operations and enables the use of high-speed automatic machine tools that may not be suitable for other materials. Cast copper alloys are fully recyclable at the end of their service life and their metal value can eventually be recovered.

There are cast versions of many of the wrought alloys, and with certain minor exceptions the properties of alloys in corresponding families, whether wrought or cast, are also generally similar.

Temper designations for cast copper alloys are listed in Table 2. Most alloys are used in the as-manufactured (as-cast) or cast-and-annealed condition, and a few can be given postcasting heat treatments to enhance mechanical or other properties.

### 9.1 Casting Methods

Selection of copper alloys for cast products should be based on the product's technical requirements. The casting's size, shape, and complexity must also be considered. The casting method can also influence alloy selection. In general, copper metals can be cast using all conventional foundry methods: sand, permanent mold, continuous, centrifugal, investment, and plaster mold. Recent advances in the pressure die-casting method, which until now has almost exclusively been restricted to low-melting-point metals, will even enable this high-rate process to be applied to copper.

The metallurgical characteristics of individual copper alloys and, sometimes, entire alloy families make them more suitable for one or more casting methods and less well suited to others. The subject is too complex to be covered adequately here, but excellent relevant publications are available from the American Foundrymen's Society (AFS), the Non-Ferrous Founders Society (NFFS), and CDA. Useful information can also be gained by discussing product requirements with an experienced foundryman.

Briefly, the way an alloy solidifies largely determines its suitability to a given process or a particular product configuration. Metals that freeze at a fixed tem-

\* Fatigue strength:  $100 \times 10^6$  cycles unless indicated as  $[N] \times 10^6$ .

perature (e.g., pure copper) or over a narrow temperature range (yellow brasses) tend to be more forgiving of solidification rate and can generally be cast by a variety of methods. Alloys with broad freezing ranges require slower solidification rates (as in sand casting) in order to avoid excessive internal porosity. These are not hard and fast rules, however, and they can often be abridged by careful design and foundry practice.

A better understanding of the importance of freezing behavior has led to a growing interest in the permanent-mold casting process in the United States. The process makes use of “permanent” metal dies that induce rapid solidification and therefore enable short cycle times and high production rates. Among the process’s other advantages are the ability to produce near net shapes, fine surface finishes, close tolerances, and exceptional part-to-part uniformity. Thin section sizes are also readily attainable. The permanent-mold process is considered friendly to the environment because it leaves virtually no residues for disposal. From the designer’s standpoint, the method’s most significant advantage is that the dense structure and fine grain size it produces results in castings having higher strength, for the same alloys, than those available in sand castings. For alloy C87500, a silicon brass, tensile strengths (TS) for sand-cast and permanent-mold cast versions are 462 MPa (67 ksi) and 562 MPa (80 ksi), respectively, a 21% difference. Table 7 contains several other examples that illustrate this phenomenon.

## 9.2 Uses

The plumbing industry is the largest user of copper castings, mainly for brass fixtures, fittings, and water meters. Among the commonly used alloys are C83600, a leaded red brass, C84400, a semired brass, and several of the yellow brasses, the latter often being specified for decorative faucets and similar hardware.

Traditional plumbing brasses contain lead to improve castability and machinability. Concerns expressed in recent years over the possibility that a portion of the lead might be leached from a plumbing fixture’s internal surfaces by aggressive water and thus enter the human food chain led to the development of several new alloys, aptly named EnviroBrasses. These brasses contain only trace amounts of lead up to a maximum of 0.25%. EnviroBrass I (C89510) and EnviroBrass II (C89520) substitute a mixture of selenium and bismuth for the lead contained in conventional red and semired brasses. EnviroBrass III (C89550) is a yellow brass that is ideally suited to the permanent-mold casting process.

Industrial pumps, valves, and fittings are other important outlets for copper alloy castings. Alloys are generally selected for favorable combinations of corrosion, wear, and mechanical properties. Popular alloys include aluminum bronze, nickel–aluminum bronze, tin bronzes, manganese bronze, and silicon bronzes and brasses.

Copper alloys have been used in marine products for centuries, and that trend continues today. The copper metals exhibit excellent general corrosion resistance in both fresh and seawater. Unlike some stainless steels, they resist pitting and stress-induced cracking in aggressive chloride environments.

Commonly selected alloys include dezincification-inhibited brasses, tin bronzes, and manganese, silicon, and aluminum bronzes. For maximum seawater corrosion resistance, copper–nickels should be considered.

Decorative architectural hardware is often cast in yellow brass. Plaques and statuary make use of the copper metals' ability to reproduce fine details, and the alloys' wide range of colors—including natural and synthetic patinas—have long been favored by artists and designers.

### 9.3 Sleeve Bearings

Sleeve bearings deserve mention here because, with the exception of oil-impregnated powder metal bearings, most bronze bearings are produced as either continuous or centrifugal castings. Design of sleeve bearings is based on design loads, operating speeds, temperature, and lubricant and lubrication mode. Selection of the optimum alloy for a particular design takes all these factors into account; however, journal hardness and alignment, possible lubricant starvation, and other unusual operating conditions must also be considered.

Tin bronzes, leaded tin bronzes, and high-leaded tin bronzes are the most commonly specified sleeve bearing alloys, alloy C93200 being considered the workhorse of the industry. Tin imparts strength; lead improves antifrictional properties but does so at the expense of some strength. High-leaded tin bronzes have the highest lubricity but the lowest strength of the bearing alloys. Aluminum bronzes and manganese bronzes are selected for applications that require very high strength and excellent corrosion resistance.

A useful primer on sleeve bearing design can be found at [http://www.copper.org/industrial/bronze\\_bearing.htm](http://www.copper.org/industrial/bronze_bearing.htm). PC-compatible sleeve bearing design software is available from CDA.

## 10 COPPER IN HUMAN HEALTH AND THE ENVIRONMENT

There has been a trend recently for engineers to take a material's health and environmental effects into account during product design, and "heavy metals" such as lead and cadmium, alone or in alloyed form, have lost favor despite whatever benefit they brought to market. While copper is chemically defined as a heavy metal, its use should give designers no concerns in this regard. Copper has, in fact, rightly been called an environmentally "green" metal.

Copper is essential to human, animal, and plant life. It is especially important to expectant mothers and infants. Without sufficient dietary intake to maintain internal stores, people suffer metabolic disorders and a variety of other problems. Animals fail to grow properly when copper is not provided in their feed or if they graze on copper-deficient plants. Crops grown on copper-deficient soils produce lower yields and some plants may simply wither and die.

On the other hand, copper does exhibit toxicity under some circumstances. This property is exploited beneficially in, for example, antifouling marine paints, agricultural fungicides, and alloys for seawater piping systems. In the United States, federal regulations limit public water supplies to copper concentrations to 1.3 parts per million (ppm)—the limit in Europe is 2.0 ppm—but higher levels found in some well waters are objectionable mainly because of the metallic taste the metal imparts. The threshold for acute physiological effects,

mainly nausea and other temporary gastrointestinal disorders, is estimated to lie between 4 and 6 ppm, although sensitivity varies widely among individuals.

There has been concern expressed over the discharge of copper in effluents from copper roofs and copper plumbing systems. Copper may exist in such effluents in minute quantities, mainly bound as chemical compounds and complexes that are not ecologically available. Such forms of copper differ from ionic copper, which can exhibit ecotoxicity but which appears to exist only briefly in nature owing to copper's very strong bonding tendency, leading it to form non-bioavailable or nontoxic chemical compounds.

Finally, the fact that almost all copper is eventually recycled into useful products deserves recognition as one of the metal's environmental benefits. Currently, about 45% of all copper in use has been used in some form before. Largely because of the metal's high value, almost none of it finds its way to landfills. Recycling not only conserves a natural resource, it also avoids re-expenditure of the energy needed for mining, smelting and, refining.

### 1 INTRODUCTION

#### 1.1 Purpose

The purpose of this chapter is to provide a reasonable understanding of titanium and its alloys so that selection of them for specific designs will be appropriate.

Knowledge of titanium alloy types and their processing should provide a potential user with a better ability to understand the ways in which titanium alloys (and titanium) can contribute to a design. Furthermore, the knowledge provided here should enable a user of titanium alloys to:

- Ask the important production questions of titanium providers.
- Specify necessary mechanical property levels to optimize alloy performance in the desired application.
- Determine the relevant corrosion/environmental factors that may affect a component.

Properties of the titanium alloy families sometimes are listed in handbooks or vendor/supplier brochures. However, not all data will be available and there is no special formula for titanium alloy selection.

Larger volume customers frequently dictate the resultant material conditions that generally will be available from a supplier. Proprietary alloy chemistries and/or proprietary/restricted processing required by customers can lead to alloys that may not be widely available. In general, proprietary processing is more likely to be encountered than proprietary chemistries nowadays. With few exceptions, critical applications for titanium and its alloys will require the customer to work with one or more titanium producers to develop an understanding of what is available and what a selector/designer can expect from a chosen titanium alloy.

## **1.2 What Are Titanium Alloys?**

Titanium alloys for purposes of this chapter are those alloys of about 50% or higher titanium that offer exceptional strength-to-density benefits plus corrosion properties comparable to the excellent corrosion resistance of pure titanium. The range of operation is from cryogenic temperatures to around 538°C (1000°F) or slightly higher. Titanium alloys based on intermetallics such as gamma titanium aluminide (TiAl intermetallic compound that has been designated  $\gamma$ ) are included in this discussion but offer no clear-cut mechanical advantages for now and an economic debit in many instances.

## **1.3 Temperature Capability of Titanium Alloys**

The melting point of titanium is in excess of 1660°C (3000°F), but commercial alloys operate at substantially lower temperatures. It is not possible to create titanium alloys that operate close to their melting temperatures. Attainable strengths, crystallographic phase transformations, and environmental interaction considerations cause restrictions. Thus, while titanium and its alloys have melting points higher than those of steels, their maximum upper useful temperatures for structural applications generally range from as low as 427°C (800°F) to the region of about 538–595°C (1000–1100°F) dependent on composition. Titanium aluminide alloys show promise for applications at temperatures up to 760°C (1400°F).

Actual application temperatures will vary with individual alloy composition. Since application temperatures are much below the melting points, incipient melting is not a factor in titanium alloy application.

1.4 Strength and Corrosion Capability of Titanium and Its Alloys

Titanium owes its industrial use to two significant factors:

- Titanium has exceptional room temperature resistance to a variety of corrosive media.
- Titanium has a relatively low density and can be strengthened to achieve outstanding properties when compared with competitive materials on a strength to density basis.

Table 1 compares typical strength-to-density values for commercial purity (CP) titanium, several titanium alloys, and a high strength steel. Figure 1 depicts the strength improvements possible in titanium alloys. In addition to the excellent strength characteristics, titanium’s corrosion resistance makes it a desirable material for body replacement parts and other tough corrosion-prone applications.

1.5 Titanium Alloy Information

While some chemistries and properties are listed in this chapter, there is no substitute for consultation with titanium manufacturers about the forms (some cast, mostly wrought) that can be provided and the exact chemistries available. It should be understood that not all titanium alloys, particularly those with specific processing, are readily available as off-the-shelf items. Design data for titanium alloys are not intended to be conveyed here, but typical properties are indicated for some materials. Design properties should be obtained from internal testing if possible, or from producers or other validated sources if sufficient test data are not available in-house. Typical properties are merely a guide for comparison. Exact chemistry, section size, heat treatment, and other processing steps must be known to generate adequate property values for design.

The properties of titanium alloy compositions that have been developed over the years are not normally well documented in the literature. However, since many consumers actually only use a few alloys within the customary user groups, data may be more plentiful for certain compositions. In the case of titanium, the most used and studied alloy, whether wrought or cast, is Ti–6Al–4V.

The extent to which data generated for specific applications are available to the general public is unknown. However, even if such data were disseminated widely, the alloy selector needs to be aware that processing operations such as forging conditions, heat treatment, etc. dramatically affect properties of titanium

Table 1 Comparison of Typical Strength-to-Weight Ratios at 20°C

| Metal                           | Specific Gravity | Tensile Strength (lb/in. <sup>2</sup> ) | Tensile Strength ÷ Specific Gravity |
|---------------------------------|------------------|-----------------------------------------|-------------------------------------|
| CP                              | 4.5              | 58,000                                  | 13,000                              |
| Ti–6Al–4V                       | 4.4              | 130,000                                 | 29,000                              |
| Ti–4Al–3Mo–1V                   | 4.5              | 200,000                                 | 45,000                              |
| Ultrahigh-strength steel (4340) | 7.9              | 287,000                                 | 36,000                              |

**Fig. 1** Yield strength-to-density ratio as a function of temperature for several titanium alloys compared to some steel, aluminum, and magnesium alloys. (From *Titanium: A Technical Guide*, 1st ed., ASM International, Materials Park, OH 44073-0002, 1988, p. 158.)

alloys. All data should be reconciled with the actual manufacturing specifications and processing conditions expected. Alloy selectors should work with competent metallurgical engineers to establish the validity of data intended for design as well as to specify the processing conditions that will be used for component production.

Application of design data must take into consideration the probability of components containing locally inhomogeneous regions. For titanium alloys, such segregation can be disastrous in gas turbine applications. The probability of occurrence of these regions is dependent upon the melting procedures, being essentially eliminated by so-called triple melt. All facets of chemistry and processing need to be considered when selecting a titanium alloy for an application.

For sources of property data other than that of the producers (melters, forgers, etc.) or an alloy selector's own institution, one may refer to handbooks or organizations, such as ASM International, that publish compilations of data that may form a basis for the development of design allowables for titanium alloys. Standards organizations such as the American Society for Testing and Materials (ASTM) publish information about titanium alloys, but that information may not ordinarily contain any design data.

## 2 METALLURGY OF TITANIUM ALLOYS

### 2.1 Structures

Metals are crystalline and the atoms take various crystallographic forms. Some of these forms tend to be associated with better property characteristics than

other crystal structures. Titanium, as does iron, exists in more than one crystallographic form. Titanium has two elemental crystal structures: in one, the atoms are arranged in a body-centered cubic array, in the other they are arranged in a close-packed hexagonal array. The cubic structure is found only at high temperatures, unless the titanium is alloyed with other elements to maintain the cubic structure at lower temperatures.

We are concerned not only with crystal structure but also overall “structure,” i.e., appearance, at levels above that of atomic crystal structure. Structure for our purposes will be defined as the macrostructure and microstructure (i.e., macro- and microappearance) of a polished and etched cross section of metal visible at magnifications up to and including 10,000 $\times$ . Two other microstructural features that are not determined visually but are determined by other means such as X-ray diffraction or chemistry are: phase type (e.g.,  $\alpha$  and  $\beta$ ) and texture (orientation) of grains.

Titanium’s two crystal structures are commonly known as  $\alpha$  and  $\beta$ . Alpha actually means any hexagonal titanium, pure or alloyed, while beta means any cubic titanium, pure or alloyed. The  $\alpha$  and  $\beta$  structures—sometimes called systems or types—are the basis for the generally accepted classes of titanium alloys. These are  $\alpha$ , near- $\alpha$ ,  $\alpha$ - $\beta$ , and  $\beta$ . Sometimes a category of near- $\beta$  is also considered. The preceding categories denote the general type of microstructure after processing.

Crystal structure and grain structure (a component of microstructure) are not synonymous terms. Both (as well as the arrangement of phases in the microstructure) must be specified to completely identify the alloy and its expected mechanical, physical, and corrosion behavior. The important fact to keep in mind is that, while grain shape and size do affect behavior, the crystal structure changes (from  $\alpha$  to  $\beta$  and back again) which occur during processing play a major role in defining titanium properties.

## 2.2 Crystal Structure Behavior in Alloys

An  $\alpha$ -alloy (so described because its chemistry favors  $\alpha$ -phase) does not normally form  $\beta$ -phase on heating. A near- $\alpha$  (sometimes called “superalpha”) alloy forms only limited  $\beta$ -phase on heating, and so it may appear microstructurally similar to an  $\alpha$ -alloy when viewed at lower temperatures. An  $\alpha$ - $\beta$  alloy is one for which the composition permits complete transformation to  $\beta$  on heating but transformation back to  $\alpha$  plus retained and/or transformed  $\beta$  at lower temperatures. A near- $\beta$  or  $\beta$ -alloy composition tends to retain, indefinitely at lower temperatures, the  $\beta$ -phase formed at high temperatures. However, the  $\beta$  that is retained on initial cooling to room temperature is metastable for many  $\beta$ -alloys. Dependent on chemistry, it may precipitate secondary phases during heat treatment.

## 3 METALS AT HIGH TEMPERATURES

### 3.1 General

While material strengths at low temperatures are usually not a function of time, at high temperatures the time of load application becomes very significant for mechanical properties. Concurrently, the availability of oxygen at high temperatures accelerates the conversion of some of the metal atoms to oxides. Oxidation

proceeds much more rapidly at high temperatures than at room or lower temperatures. For alloys of titanium there is the additional complication of titanium's high affinity for oxygen and its ability to "getter" oxygen (or nitrogen) from the air. Dissolved oxygen greatly changes the strength and ductility of titanium alloys. Hydrogen is another gaseous element that can significantly affect properties of titanium alloys. Hydrogen tends to cause hydrogen embrittlement while oxygen (and nitrogen) will increase strength and reduce the ductility but not necessarily embrittle titanium as hydrogen does.

### 3.2 Mechanical Behavior

In the case of short-time tensile properties of yield strength (TYS) and ultimate strength (UTS), the mechanical behavior of metals at higher temperatures is similar to that at room temperature but with metals becoming weaker as the temperature increases. However, when steady loads below the normal yield or ultimate strength determined in short-time tests are applied for prolonged times at higher temperatures, the situation is different. Figure 2 illustrates the way in which most materials respond to steady extended-time loads at high temperatures. A time-dependent extension (creep) is noticed under load. If the alloy is exposed for a long time, the alloy eventually fractures (ruptures). The degradation process is called creep or, in the event of failure, creep-rupture (sometimes stress-rupture), and alloys are selected on their ability to resist creep and creep-rupture failure. Cyclically applied loads that cause failure (fatigue) at lower temperatures also cause failures in shorter times (lesser cycles) at high temperatures. When titanium alloys operate for prolonged times at high temperature, they can fail by creep-rupture. However, tensile strengths, fatigue strengths, and crack propagation criteria are more likely to dominate titanium alloy performance requirements.

**Fig. 2** Creep rupture schematic showing time-dependent deformation under constant load at constant high temperatures followed by final rupture. (All loads below the short time yield strength. Roman numerals denote ranges of the creep rupture curve.)

In highly mechanically loaded parts, such as gas turbine compressor disks, a common titanium alloy application, fatigue at high loads in short times, low cycle fatigue (LCF) is the major concern. High cycle fatigue (HCF) normally is not a problem with titanium alloys unless a design error occurs and subjects a component to a high-frequency vibration that forces rapid accumulation of fatigue cycles. While life under cyclic load ( $S$ - $N$  behavior) is a common criterion for design, resistance to crack propagation is an increasingly desired property. Thus, the crack growth rate versus a fracture toughness parameter is required. The parameter in this instance is the stress intensity factor ( $K$ ) range over an incremental distance which a crack has grown—the difference between the maximum and minimum  $K$  in the region of crack length measured. A plot of the resultant type ( $da/dN$  vs.  $\Delta K$ ) is shown in Fig. 3 for several wrought titanium alloys.

For Ti-10V-2Fe-3Al:  $R = 0.05$ ;  $F = 1-30$  Hz

For MA Ti-6Al-4V:  $R = 0.08$ ;  $F = 1-25$  Hz

For RA Ti-6Al-4V:  $R = 0.08$ ;  $F = 6$  Hz

**Fig. 3** Comparison of fatigue crack growth rate ( $da/dN$ ) vs. toughness change ( $\Delta K$ ). Curves for several titanium alloys. Note that MA = mill annealed while RA = recrystallization annealed.

(From *Titanium: A Technical Guide*, 1st ed., ASM International, Materials Park, OH 44073-0002, 1988, p. 184.)

## 4 MICROSTRUCTURE AND PROPERTIES OF TITANIUM AND ITS ALLOYS

The grain size, grain shape, and grain boundary arrangements in titanium have a very significant influence on mechanical properties, and it is the ability to manipulate the phases/grains present as a result of alloy composition that is responsible for the variety of properties that can be produced in titanium and its alloys. Transformed  $\beta$ -phase products in alloys can affect tensile strengths, ductility, toughness, and cyclic properties. To these effects, must be added the basic strengthening effects of alloy elements.

### 4.1 Alloy Composition and General Behavior

Alpha alloys usually have high amounts of aluminum that contribute to oxidation resistance at high temperatures. ( $\alpha$ - $\beta$  alloys also contain, as the principal element, high amounts of aluminum, but the primary reason is to control the  $\alpha$ -phase.) Alpha alloys cannot be heat treated to develop higher mechanical properties because they are single-phase alloys.

The addition of certain alloy elements to pure titanium provides for a wide two-phase  $\alpha$  plus  $\beta$  region and so enables the resultant alloys to be heat treated or processed in the temperature range where the alloy is two phase. The two-phase condition permits the structure to be refined by the  $\alpha$  to  $\beta$  to  $\alpha$  transformation process on heating and cooling. The process of heating to a high temperature to promote subsequent transformation is known as solution heat treatment. By permitting some beta to be retained temporarily at lower temperature, the alloy elements enable optimum control of the microstructure during subsequent transformation after cooling from the forging or solution heat treatment temperature when the alloys are “aged” (reheated after rapid cooling to temperatures well below the  $\beta$  transus). The  $\alpha$ - $\beta$  alloys, when properly treated, have an excellent combination of strength and ductility. They are stronger than the  $\alpha$  or the  $\beta$ -alloys.

The  $\beta$ -alloys are metastable; that is, they tend to transform to an equilibrium, or balance, of structures. The  $\beta$ -alloys generate their strength from the intrinsic strength of the  $\beta$  structure and the precipitation of alpha and other phases from the alloy through heat treatment after processing. The most significant benefit provided by a beta structure is the increased formability of such alloys relative to the hexagonal crystal structure types ( $\alpha$  and  $\alpha$ - $\beta$ ).

Titanium aluminides differ from conventional titanium alloys in that they are principally chemical compounds alloyed to enhance strength, formability, etc. The aluminides have higher operational temperatures than conventional titanium but at higher cost and, generally, have lower ductility and formability.

In addition to alloys, titanium is sold and used in (CP) forms usually identified as grades. Pure titanium usually has some amount of oxygen alloyed with it. The strength of CP titanium is affected by the interstitial (oxygen and nitrogen) element content. A principal difference among grades is the oxygen (and nitrogen) content, which influences mechanical properties. Small additions of some alloy elements such as palladium are added for increased corrosion resistance in certain grades. A summary of the compositions of many commercial and semicommercial titanium grades and alloys is given in Table 2.

Table 2 Some Commercial and Semicommercial Grades and Alloys of Titanium

| Designation                           | Tensile Strength<br>(min) |     | 0.2% Yield Strength<br>(min) |     | Impurity Limits wt. % (max) |      |        |      |              | Nominal Composition, wt. % |     |     |     |               |
|---------------------------------------|---------------------------|-----|------------------------------|-----|-----------------------------|------|--------|------|--------------|----------------------------|-----|-----|-----|---------------|

## 4.2 Strengthening of Titanium Alloys

Desired mechanical properties such as yield or ultimate strength density (strength efficiency), perhaps creep and creep-rupture strength, as well as fatigue-crack growth rate, fracture toughness, and manufacturing considerations such as welding and forming requirements, are extremely important. They normally provide the criteria that determine the alloy composition, structure ( $\alpha$ ,  $\alpha$ - $\beta$ , or  $\beta$ ), heat treatment (some variant of either annealing or solution treating and aging), and level of process control selected or prescribed for structural titanium alloy applications.

By introducing atoms, phases, grain boundaries, or other interfaces into titanium, the movement of imperfections that cause deformation to occur is inhibited. Modification of composition and microstructure enables titanium alloys to be strengthened significantly. Final strength is a function of composition and the various deformation processes used to form and strengthen alloys. It is quite important for the alloy selector to have a realistic understanding of the strengthening process in titanium alloys as the properties of titanium and its alloys can be modified considerably not only by chemistry modification but also by processing.

The titanium alloys derive their strength from a fineness of microstructure produced by transformation of crystal structures in grains from  $\beta$  to  $\alpha$ , plus dispersion of one phase in another as in the case of precipitation of  $\alpha$ -phases from retained  $\beta$  in metastable beta alloys. The fine structure produced by transformations can often be martensitic in nature, as temperatures on the component being produced are reduced during cooling from deformation processing or solution treatment. The reader may recall that martensitic structures are produced in steels (and in other systems) and can create very strong and hard alloys. Martensitic reactions are found in titanium alloys; they are not as effective as those in steels at causing hardening but do bring about microstructure refinements and thus strength improvements in titanium alloys. Fine dispersions in the alloys usually are produced by “aging” through reheating and holding at an intermediate temperature after prior forging and heat treatment processing.

## 5 EFFECTS OF ALLOY ELEMENTS

Alloy elements generally can be classified as  $\alpha$  stabilizers or  $\beta$  stabilizers. Alpha stabilizers, such as aluminum, oxygen, and nitrogen increase the temperature at which the  $\alpha$ -phase is stable. On the other hand, beta stabilizers, such as vanadium and molybdenum, result in stability of the  $\beta$ -phase at lower temperatures. The transformation temperature from  $\alpha$  plus  $\beta$  or from  $\alpha$  to all  $\beta$  is known as the  $\beta$  transus temperature. The  $\beta$  transus is defined as the lowest equilibrium temperature at which the material is 100%  $\beta$ . The  $\beta$  transus is critical in deformation processing and in heat treatment, as described below. By reference to the  $\beta$  transus, heat treatment temperatures can produce specific microstructures during the heat treatment process. See, for example, the amount of  $\alpha$ -phase that can be produced by temperature location relative to the  $\beta$  transus for Ti-6Al-4V as shown in Fig. 4.

### 5.1 Intermetallic Compounds and Other Secondary Phases

Intermetallic compounds and transient secondary phases are formed in titanium alloy systems along with microstructural variants of the traditional  $\beta$ - and  $\alpha$ -

**Fig. 4** Phase diagram that predicts the results of heat treatment or forging practice.  
(From *Titanium: A Technical Guide*, 1st ed., ASM International, Materials Park, OH 44073-0002, 1988, p. 51.)

phases. The more important secondary phases, historically, have been  $\omega$  and  $\alpha$ -2, chemically written as  $\text{Ti}_3\text{Al}$ . Omega phase has not proven to be a factor in commercial systems using present-day processing practice. Alpha-2 has been considered to be a concern in some cases of stress-corrosion cracking. Alloys with extra-high aluminum (favoring  $\alpha$ -2) were found to be prone to stress-corrosion cracking. Most present interest in  $\alpha$ -2 centers on its use as a matrix for a high-temperature titanium alloy. Another phase more likely to succeed as a high-temperature alloy matrix is  $\gamma$  TiAl, mentioned previously. Gamma-phase is not a factor in the property behavior of conventional titanium alloys.

## 5.2 Mechanical and Physical Properties

Titanium is a low-density element (approximately 60% of the density of steel and superalloys) that can be strengthened greatly by alloying and deformation processing. The physical and mechanical properties of elemental titanium are given in Table 3. Titanium is nonmagnetic and has good heat-transfer properties. Its coefficient of thermal expansion is somewhat lower than that of steel's and less than half that of aluminum.

Titanium's modulus can vary with alloy type ( $\beta$  vs.  $\alpha$ ) and processing from as low as about 93 GPa ( $13.5 \times 10^6$  psi) up to about 120.5 GPa ( $17.5 \times 10^6$  psi). For reference, titanium alloy moduli on average are about 50% greater than the moduli for aluminum alloys but only about 50%–60% of the moduli for steels and nickel-base superalloys. Titanium alloys can have their crystals ori-

ented by processing such that a texture develops. When that happens, instead of the usual random orientation of grains leading to uniformity of mechanical properties, a nonuniform orientation occurs and leads to a greater range of values than expected. By appropriate processing, it should be possible to orient wrought titanium for optimum elastic modulus at the high end of the modulus values quoted above. Although textures can be produced, processing that leads to di-

rectional grain or crystal orientation similar to directional solidification in castings or directional recrystallization in oxide dispersion strengthened alloys is not practical in titanium alloy systems.

5.3 Effects of Processing

Properties of titanium alloys generally are controlled by variations of the processing (including heat treatment) and are modified for optimum fatigue resistance by surface treatments such as shot peening. Process treatments can produce either acicular or equiaxed microstructures in most titanium alloys if phase transformations from  $\alpha$  to  $\beta$  to  $\alpha$  or related phases are permitted to occur. Microstructures have been identified that show  $\alpha$  as acicular or equiaxed and with varying amounts of  $\alpha$ -phase. The platelike or acicular  $\alpha$  produced by transformation from  $\beta$ -phase has special aspects as far as properties are concerned. Table 4 shows the relative behavior of equiaxed versus platelike alpha. No one microstructure is good for all applications.

5.4 Hydrogen (in CP Titanium)

The solubility of hydrogen in  $\alpha$  titanium at 300°C (572°F) is about 8 at. % (about 0.15 wt. %, or about 1000 ppm by weight). Hydrogen in solution has little effect on the mechanical properties. Damage is caused by hydrides which form. Upon precipitation of the hydride, the ductility suffers. Hydrogen damage of titanium and titanium alloys, therefore, is manifested as a loss of ductility (embrittlement) and/or a reduction in the stress intensity threshold for crack propagation. Figure 5 shows the effect of hydrogen on reduction of area, a measure of ductility.

No embrittlement is found at 20 ppm hydrogen, which corresponds to about 0.1 at. % of hydrogen. Other data shows that, independent of the heat treatment, this low a concentration has little effect on the impact strength (a different measure of embrittlement). However, as little as 0.5 at. % hydrogen (about 100 atom ppm) can cause measurable embrittlement. Slow cooling from the  $\alpha$  region—e.g. 400°C (752°F)—allows sufficient hydride to precipitate to reduce the impact energy. The only practical approach to control the hydrogen problem is to maintain a low concentration of the element. As a result, CP titanium will usually have a maximum allowable hydrogen content of about 0.015 wt. % (about 100 ppm by weight). For example, for the grades of commercially pure

**Table 4   Relative Advantages of Equiaxed and Acicular Microstructures**

**Fig. 5** Ductility of alpha titanium versus test temperature, showing embrittling effects of hydrogen. (From *Titanium: A Technical Guide*, 1st ed., ASM International, Materials Park, OH 44073-0002, 1988, p. 161.)

titanium, the level is about 0.01%. Hydrogen also can have a potent effect on titanium alloy properties.

### 5.5 Oxygen and Nitrogen (in CP Titanium)

Oxygen and nitrogen have a significant effect on strength properties. As the amount of oxygen and nitrogen increases, the toughness decreases until the material eventually becomes quite brittle. Embrittlement occurs at a concentration considerably below the solubility limit. The allowed oxygen content is higher than the allowed nitrogen content. Yield and ultimate strengths increase as oxygen (and nitrogen) levels go up. The higher strengths in CP titanium grades come from higher oxygen levels. Oxygen (and nitrogen) can have a potent effect on titanium alloy properties as well.

### 5.6 Mechanical Properties of Titanium Alloys

The grain size, grain shape, and grain boundary arrangements in titanium have a very significant influence on mechanical properties, and it is the ability to manipulate the phases/grains present as a result of alloy composition that is responsible for the variety of properties that can be produced in titanium and its alloys. Transformed  $\beta$ -phase products in alloys can affect tensile strengths, ductility, toughness, and cyclic properties. To these effects must be added the basic strengthening effects of alloy elements.

Interstitial elements are those elements such as oxygen that are significantly smaller than the titanium atom and so may dissolve in the titanium phase crystal lattice as solid solutions without substituting for titanium atoms. Of course, some interstitial elements also may form second phases with titanium. As is the case for comparable-size elements, interstitial elements may have a preference for

one phase over another in titanium. As indicated above, a significant influence on mechanical behavior of CP titanium is brought about by hydrogen, nitrogen, carbon, and oxygen, which dissolve interstitially in titanium and have a potent effect on mechanical properties. These effects carry over to titanium alloys in varying degrees.

The ELI (extra-low interstitial) levels specified for some titanium alloys implicitly recognize the effect of reduced interstitials on ductility. ELI-type material is used for critical applications where enhanced ductility and toughness are produced by keeping interstitials at a very low level. Hydrogen is always kept at a low level to avoid embrittlement, yet there still remains concern about the most reasonable level to specify in both CP and alloyed titanium to protect against embrittlement but keep manufacturing cost low.

Although data are not provided here for grain size effects on titanium grades, it is generally accepted that fineness of structure (smaller particle size, grain size, etc.) is more desirable from the point of view of TYS in metallic materials. The UTS is not particularly affected by grain size, but ductility as represented by elongation or reduction in area generally is improved with smaller grain sizes. Ductility is a measure of toughness, but toughness is not normally at issue in CP titanium grades. Another measure of toughness is Charpy impact strength. Chemistry and minimum tensile properties for various specifications for CP and modified titanium grades at room temperature are given in Table 5.

Elevated temperature behavior of titanium grades has been studied, but titanium grades are not customarily used at high temperatures. The near- $\alpha$  or  $\alpha$ - $\beta$  alloys are the preferred materials where high-temperature mechanical properties are desired. With allowance for grain size effects and possible minor chemistry variations, cast CP titanium materials should behave in much the same way as wrought.

### Alpha Alloys

Alpha alloys such as Ti-5Al-2.5Sn, Ti-6Al-2Sn-4Zr-2Mo + Si and Ti-8Al-1Mo-1V (see Table 2) are used primarily in gas turbine applications. Ti-8Al-1Mo-1V alloy and Ti-6Al-2Sn-4Zr-2Mo + Si are useful at temperatures above the normal range for the workhorse  $\alpha$ - $\beta$  alloy, Ti-6Al-4V. Ti-8Al-1Mo-1V and Ti-6Al-2Sn-4Zr-2Mo + Si alloys have better creep resistance than Ti-6Al-4V, and creep resistance is enhanced with a fine acicular (Widmanstätten) structure. In its normal heat-treated condition, Ti-6Al-2Sn-4Zr-2Mo + Si alloy actually has a structure better described as  $\alpha$ - $\beta$ .

Alpha and near- $\alpha$  alloys therefore are usually employed in the solution annealed and stabilized condition. Solution annealing may be done at a temperature some 35°C (63°F) below the  $\beta$  transus temperature while stabilization is commonly produced by heating for 8 h at about 590°C (1100°F). These alloys are more susceptible to the formation of ordered  $\text{Ti}_3\text{Al}$ , which promotes stress-corrosion cracking (SCC).

### Alpha-Beta Alloys

The most important titanium alloy is the  $\alpha$ - $\beta$  alloy, Ti-6Al-4V. This alloy has found application for a wide variety of aerospace components and fracture-critical parts. With a strength-to-density ratio of  $25 \times 10^6 \text{ mm}$  ( $1 \times 10^6 \text{ in.}$ ),

**Table 5 CP and Modified Ti: Minimum Room Temperature Tensile Properties for Various Specifications**

Ti-6Al-4V is an effective lightweight structural material and has strength-toughness combinations between those of steel and aluminum alloys. High-strength  $\alpha$ - $\beta$  alloys include Ti-6Al-6V-2Sn and Ti-6Al-2Sn-4Zr-6Mo. Alpha is the dominant phase in all of these alloys but is dominant to a lesser extent in the high-strength alloys than in Ti-6Al-4V. These high-strength alloys are stronger and more readily heat treated than Ti-6Al-4V.

When  $\alpha$ - $\beta$  titanium alloys are heat treated high in the  $\alpha$ - $\beta$  range, and then cooled, the resulting structure, because of the presence of globular (equiaxed) primary  $\alpha$  in the transformed  $\beta$  (platelike) matrix is called equiaxed. When a 100% transformed  $\beta$  structure is achieved by cooling from above the  $\beta$  transus, the structure may be called acicular, or needlelike. Generally speaking,  $\alpha$ - $\beta$  alloys would be annealed just below the  $\beta$  transus to produce a maximum of transformed acicular  $\beta$  with approximately 10% of equiaxed  $\alpha$  present. Some titanium alloys—for example, Ti-6Al-2Sn-4Zr-2Mo—are given  $\beta$  heat treatments to enhance high-temperature creep resistance. (Castings and powder products may be given a  $\beta$  anneal, too, in order to break up the structure, although not necessarily for optimizing creep strength.)

In actual components, the structure of titanium  $\alpha$ - $\beta$  type of alloys is controlled not only by how much working is done and by how close to, or above, the  $\beta$  transus the alloy is processed, but also by the section size of the component. Ideally, alloys should have good hardenability, i.e., ability to reach desired cooling rates and attendant microstructures in fairly thick sections. Many  $\alpha$ - $\beta$  alloys do not have great hardenability. Ti-6Al-4V alloy only has sufficient hardenability to be effectively heat treated to full property levels in sections less than 25 mm (1 in.) thick.

One of the least understood concepts in the behavior of  $\alpha$ - $\beta$  titanium alloys is that of aging. With few exceptions titanium alloys do not age in the classical sense—that is, where a secondary, strong intermetallic compound appears and strengthens the matrix by its dispersion. A dispersion is produced, on aging of  $\alpha$ - $\beta$  alloys, but it is thought to be  $\beta$  dispersed in the  $\alpha$  or martensitic alpha prime. Beta is not materially different from  $\alpha$  phase with respect to strength; however, the effectiveness of strengthening in titanium alloys appears to center in the number and fineness of  $\alpha$ - $\beta$  phase boundaries. Annealing and rapid cooling, which maximize  $\alpha$ - $\beta$  boundaries for a fixed primary  $\alpha$  content, along with aging, which may promote additional boundary structure, can significantly increase alloy strength.

### Beta Alloys

An alloy is a  $\beta$ -alloy if it contains sufficient  $\beta$  stabilizer alloying element to retain the  $\beta$ -phase without transformation to martensite on quenching to room temperature. A number of titanium alloys (see Table 2) contain more than this minimum amount of  $\beta$  stabilizer alloy addition. The more highly  $\beta$  stabilized alloys are alloys such as Ti-3Al-8V-6Cr-4Mo-4Zr (beta C) and Ti-15V-3Cr-3Al-3Sn. Solute-lean  $\beta$  alloys are sometimes classified as  $\beta$ -rich  $\alpha$ - $\beta$  alloys, and this class includes Ti-10V-2Fe-3Al and proprietary alloys such as Ti-17 (Ti-5Al-2Sn-2Zr-4Mo-4Cr) and beta CEZ (Ti-5Al-2Sn-4Zr-4Mo-2Cr).

In a strict sense there is no truly stable  $\beta$ -alloy because even the most highly alloyed  $\beta$  will, on holding at elevated temperatures, begin to precipitate  $\omega$ ,  $\alpha$ ,

Ti<sub>3</sub>Al, or silicides, depending on temperature, time, and alloy composition. All  $\beta$ -alloys contain a small amount of aluminum, an  $\alpha$  stabilizer, to strengthen  $\alpha$  that may be present after heat treatment. The composition of the precipitating  $\alpha$  is not constant and will depend on the temperature of heat treatment. The higher the temperature in the  $\alpha$ - $\beta$  phase field, the higher will be the aluminum content of  $\alpha$ .

The processing window is tighter than that normally used for the other alloy types ( $\alpha$  and  $\alpha$ - $\beta$  alloys). For the less highly  $\beta$  stabilized alloys, such as Ti-10V-2Fe-3Al, for example, the thermomechanical process is critical to the property combinations achieved as this has a strong influence on the final microstructure and the resultant tensile strength and fracture toughness that may be achieved. Exacting control of thermomechanical processing is somewhat less important in the more highly  $\beta$  stabilized alloys, such as Ti-3Al-8V-6Cr-4Mo-4Zr and Ti-15V-3Cr-3Al-3Sn. In these alloys, the final microstructure, precipitated  $\alpha$  in the  $\beta$  phase, is so fine that microstructural manipulation through thermomechanical processing is not as effective.

## Properties

***Wrought Alloys.*** Typical room temperature property values for titanium alloy mill products are listed in Table 6. Fractions of room temperature strength retained at elevated temperatures by the same titanium alloys are shown in Table 7. Data for unalloyed titanium are included in Table 7 to illustrate that the alloys not only have higher room temperature strengths than unalloyed titanium but also retain much larger fractions of that strength at elevated temperatures. Typical tensile strengths and 0.1% creep strengths as functions of temperature of some selected alloys are shown in Figs. 6 and 7, respectively.

Fatigue life in unalloyed titanium depends on grain size, interstitial (oxygen, etc.) level, and degree of cold work, as illustrated in Fig. 8. A decrease in grain size in unalloyed titanium from 110  $\mu\text{m}$  down to 6  $\mu\text{m}$  improves the  $10^7$  cycle fatigue endurance limit by 30%. HCF endurance limits of unalloyed titanium depend on interstitial contents just as do the YS and UTS. The ratio of HCF endurance limit and YS at ambient temperature appears to remain relatively constant as YS changes with interstitial content but does show a temperature dependence.

There are significant differences among titanium alloys in fracture toughness, but there is also appreciable overlap in their properties. Table 8 gives examples of typical plane-strain fracture toughness ranges for  $\alpha$ - $\beta$  titanium alloys. From these data it is apparent that the basic alloy chemistry affects the relationship between strength and toughness. From Table 8 it is also evident, as noted earlier, that transformed microstructures may greatly enhance toughness while only slightly reducing strength. It is well known that toughness depends on thermomechanical processing (TMP) to provide the desired structure. However, the enhancement of fracture toughness at one stage of an operation—for example, a forging billet—does not necessarily carry over to a forged part. Because welds in alloy Ti-6Al-4V contain transformed products, one would expect such welds to be relatively high in toughness. This is, in fact, the case. In addition to welding, many other factors such as environment, cooling rates in large sections (i.e.,

Table 6 Tensile Strengths of Several Commercial Titanium-Base Alloys: Typical Room Temperature Values

hardenability, a factor that affects structural fineness), hydrogen content, etc. may affect  $K_{Ic}$ .

Titanium alloys may show less resistance to notches than other alloys. Notch strength in fatigue is significantly lower than smooth strength. Scratches on the surfaces of titanium alloy components can lead to reduced fatigue capability. High levels of favorable compressive residual stresses usually exist in titanium alloys as a result of machining. These levels are sometimes enhanced by surface processing such as glass bead or shot peening.

**Cast Alloys.** Cast-titanium alloys are generally  $\alpha$ - $\beta$  alloys. They are equal, or nearly equal, in strength to wrought alloys of the same compositions. Typical room temperature tensile properties of several cast-titanium alloys are shown in Table 9 while creep strength of cast Ti-6Al-4V is shown in Table 10. Virtually all existing data have been generated from alloy Ti-6Al-4V; consequently, the basis for most cast-alloy property data is Ti-6Al-4V. Because the microstructure of cast-titanium alloy parts is comparable to that of wrought material, many properties of cast plus HIP parts are at similar levels to those for wrought alloys. These properties include tensile strength, creep strength, fracture toughness, and fatigue crack propagation.

Generally, castings of titanium alloys are hot isostatically pressed (HIP) to close casting porosity. HIP conditions may affect the resultant properties as HIP is just another heat treatment as far as microstructure is concerned. It also should be noted that test results are often on small separately cast test coupons and will

**Note:** Specimens from hubs of centrifugal compressor impellers that were cast, HIPed (2 h at 900°C, or 1650°F), and 103.5 MPa, 15.0 ksi, and aged 1.5 h at 675°C (1250°F). Specimen blanks approximately 5.72 by 0.95 by 0.96 cm (2.25 by 0.37 by 0.37 in.) in section size, with the long axis oriented tangential to the hub section, were machined to standard-type creep specimens 3.81 mm (0.150 in.) in diameter. The specimens were lathe turned and then polished with 320-grit emery paper. The creep-rupture tests were performed at 120–455°C (250–850°F) using dead-load-type creep frames in air over a stress ranged of 276–552 MPa (40–80 ksi). The microstructure consisted of transformed  $\beta$  grains with discontinuous grain-boundary  $\alpha$  and colonies of transformed  $\beta$  that contained packets of parallel-oriented  $\alpha$  platelets separated by a thin layer of aged  $\beta$ .

**Source:** A. Chakrabarti and E. Nichols, Creep Behavior of Cast Ti-6Al-4V Alloy, *Titanium '80: Science and Technology*, Proceedings of the 4th International Conference on Titanium, Kyoto, Japan, 19–22 May 1980, Vol. 2, H. Kimura and O. Izumi, Ed., TMS/AIME, 1980, pp. 1081–1096.

not necessarily reflect the property level achievable with similar processing on a full-scale cast part. Property levels of actual cast parts, especially larger components, probably will be somewhat lower, the result of coarser grain structure or slower quench rates achieved.

**Summary.** Powder metallurgy technology has been applied to titanium alloy processing with limited success, partially owing to economic issues. Wrought processing remains the preferred method of achieving shape and property control. Cast alloy processing is used but for a limited alloy base. Figure 9 shows fatigue scatter bands for wrought, cast, and powder metallurgy products of Ti-6Al-4V alloy for comparison of attainable properties.

6 MANUFACTURING PROCESSES

6.1 General Aspects of the Manufacture of Titanium Articles

Appropriate compositions of titanium can be forged, rolled to sheet, or otherwise formed into a variety of shapes. Some compositions can be processed as large investment castings. Commercial large castings are made mostly in the titanium alloy Ti-6Al-4V, which has been in production for over 40 years. Fabricated titanium structures can be built up by welding or brazing. Fabricated structures are primarily made with Ti-6Al-4V. Fabricated structures may contain cast as

**Fig. 9** Fatigue scatter bands for ingot metallurgy, castings, and powder metallurgy products of Ti-6Al-4V alloy. (From *Titanium: A Technical Guide*, 2nd ed., ASM International, Materials Park, OH 44073-0002, 2001, p. 116.)

well as wrought parts, although wrought components are used for most applications.

Single-piece forged gas turbine fan and compressor disks are prime applications for titanium alloys. Titanium wrought, cast, and powder metallurgy products find use in the biomedical arena. Fan blades and compressor blades of titanium represent areas that continue to receive support despite the reported threat from composites. By and large, most titanium alloys are wrought, in particular, forged.

The manufacture of titanium alloys consists of a number of separate steps of which the following represent the transfer of titanium from an ore to an ingot ready for either wrought or cast processing or to mill products:

- Production of titanium sponge (reduction of titanium ore to an impure porous form of titanium metal)
- Purification of the sponge
- Melting of sponge or sponge plus alloy elements or a master alloy to form an electrode
- Remelting and, possibly, remelting again to homogenize the first electrode and create an ingot for further processing
- Primary fabrication, in which ingots are converted into billets or general mill products such as bar, plate, sheet, strip, or wire
- Secondary fabrication where a billet or bar may be forged into an approximate final shape

## 6.2 Production of Titanium via Vacuum Arc Melting

Whether the final product is to be a forged or investment cast one, the essence of a titanium alloy's ability to create the properties desired hinges on the correct

application of melting principles. Melting practices may be classified as either primary (the initial melt of elemental materials and/or scrap which sets the composition) or secondary (remelt, often more than once, of a primary melt for the purpose of controlling the solidification structure). The melt type or combination of melt types selected depends upon the alloy composition, mill form and size desired, properties desired, and sensitivity of the final component to localized inhomogeneity in the alloy.

The principal method for the production of titanium electrodes and ingots since commercial introduction of titanium alloys occurred in the 1950s has been the use of vacuum arc remelting (VAR). The purity of the titanium alloys produced is a function of the purity of the starting materials. Control of raw materials is extremely important in producing titanium and its alloys because there are many elements of which even small amounts can produce major, and at times undesirable, effects on the properties of these metals in finished form. To produce ingots of titanium or its alloys for commercial application, titanium from sponge is commonly alloyed with pure other elements, master melt of titanium plus alloy elements, and/or reclaimed titanium scrap (usually called “revert”).

Because sponge is an uneven product consisting of a loose, granular mass, it does not compact as well as might be desired in some instances. Compacting is needed to make an electrode from which to melt the alloy. During melting, a piece of the sponge might fall unmelted into the solidifying electrode. Perhaps a chunk of revert or master melt might fall in. Whatever the situation, a gross inhomogeneity would result. Depending on the type and size of the inhomogeneity, a major structural defect could exist. Consequently, after some significant incidents in aircraft gas turbine engines about 30–40 years ago, second and then third melts were instituted to provide almost certain homogenization of the alloy.

Defects have been a concern for titanium ingot metallurgy production since the early days of the industry. Different types of defects were recognized, most stemming from sponge handling, electrode preparation, and melt practice. The principal characterization of these defects was as low-density inclusions (LDI) and high-density inclusions (HDI). Over two dozen different defects have been cataloged. Defects prompted strict process controls that were agreed upon jointly by metal suppliers and customers alike. These controls have done much to attain either reduced-defect or defect-free materials. Despite the controls, occasional defects have been involved in significant events of titanium-alloy-related failures. It is predicted that the introduction of cold-hearth technologies will further reduce the incidence of defects in titanium ingots. Electron beam and plasma arc melting technologies are now available for the melting of titanium alloys or the remelting of scrap. The use of these technologies permits the controlled hearth melting (CHM) of titanium alloys. Studies on electron-beam cold-hearth melting (EBCHM) and plasma arc melting (PAM) demonstrated the ability of hearth melting to remove HDI with great confidence. LDI are also addressed by CHM.

### 6.3 Forging Titanium Alloys

Manufacturing processes such as die forging, hot and cold forming, machining, chemical milling, joining, and sometimes, extrusion are all secondary fabrication processes used for producing finished parts from billet or mill products. Each

of these processes may strongly influence properties of titanium and its alloys, either alone or by interacting with effects of processes to which the metal has previously been subjected. Titanium alloy forgings are produced by all the forging methods currently available. These include open-die, closed-die, rotary forging, and others. One of the main purposes of forging, in addition to shape control, is to obtain a combination of mechanical properties that generally does not exist in bar or billet. Tensile strength, creep resistance, fatigue strength, and toughness all may be better in forgings than in bar or other forms. Selection of the optimal forging method is based on the shape desired for the forged component as well as its desired mechanical properties and microstructure (which largely determines properties after alloy composition is set).

Open-die forging is used to produce some shapes in titanium when volume and/or size do not warrant the development of closed dies for a particular application. However, closed-die forging is used to produce the greatest amount of forged titanium alloys. Closed-die forging can be classified as blocker-type (single die set), conventional (two or more die sets), or high definition (two or more die sets). Precision die forging is also conducted, usually employing hot-die/isothermal forging techniques. Conventional closed-die titanium forgings cost more than the blocker-type, but the increase in cost is justified because of reduced machining costs and better property control. The dies used in titanium forging are heated to facilitate the forging process and to reduce surface chilling and metal temperature losses that can lead to inadequate die filling and/or excessive surface cracking of the forged component. Hot-die/isothermal forging takes the die temperature to higher levels.

Forging is more than just a shape-making process. The key to successful forging and heat treatment is the  $\beta$  transus temperature. Fundamentally, there are two principal approaches to the forging of titanium alloys:

- Forging the alloy predominantly below the  $\beta$  transus
- Forging the alloy predominantly above the  $\beta$  transus

Conventional  $\alpha$ - $\beta$  forging is best described as a forging process in which all or most of the deformation is conducted below the  $\beta$  transus. Alpha,  $\beta$  and transformed  $\beta$ -phases will be present in the microstructure at some time. Structures resulting from  $\alpha$ - $\beta$  forging are characterized by deformed or equiaxed primary  $\alpha$ -phase ( $\alpha$  present during the forging process) and transformed  $\beta$  phase (acicular in appearance). Beta forging is a forging technique in which the deformation of the alloy is done above the  $\beta$  transus. In commercial practice,  $\beta$  forging actually involves initial deformation above the  $\beta$  transus but final finishing with controlled amounts of deformation below the  $\beta$  transus of the alloy. In  $\beta$  forging, the influences of mechanical working (deformation) are not necessarily cumulative because of the high temperature and because of the formation of new grains by recrystallization each time the  $\beta$  transus is surpassed on reheating for forging. Beta forging, particularly of  $\alpha$  and  $\alpha$ - $\beta$  alloys, results in significant reductions in forging pressures and reduced cracking tendency of the billet during forging.

An alternative titanium die forging procedure involves the use of precision isothermal (sometimes superplastic) forging techniques. Precision isothermal

forging produces a product form that requires much less machining than conventionally forged alloy to achieve final dimensions of the component. Precision-forged titanium is a significant factor in titanium usage in the aircraft and gas turbine engine field. Most precision-forged titanium is produced as near-net shape (NNS) products, meaning that the forging is close to final dimensions but that some machining is required.

Superplastic forming, a variant of superplastic isothermal forging, currently is widely used in the aircraft industry and to a lesser extent is used in the gas turbine industry. Advantages of superplastic forming are, among others:

- Very complex parts can be formed.
- Lighter, more efficient structures can be designed and formed.
- It is performed in a single operation.
- More than one piece may be produced in a machine cycle.
- Pressure (force) is uniformly applied to all areas of the workpiece.

Superplastic forming coupled with diffusion bonding (SPFDB) has been used on titanium alloys to produce complex fabricated structures.

#### 6.4 Investment Casting

Cost factors associated with wrought alloy processing led to continual efforts to develop and improve casting methods for titanium and its alloys. The result has been a somewhat checkered application of titanium castings with a more widespread acceptance of the practice in the last decade of the twentieth century. Titanium castings now are used extensively in the aerospace industry and to lesser measure in the chemical process, marine, biomedical, automotive, and other industries. The investment casting process uses a disposable mold to create a negative image of the desired component. Metal fills the mold and solidifies with the desired shape and dimensions very close to final desired values. Some machining is necessary.

Several alloys were studied at first, but soon investigators concentrated on Ti-6Al-4V with results that supported an idea that cast-titanium parts could be made with strength levels and characteristics approaching those of conventional wrought alloys. Subsequently, additional titanium components have successfully been cast from pure titanium,  $\alpha$ - $\beta$  and  $\beta$ -alloys. Nonetheless, the primary alloy used for casting of titanium components is Ti-6Al-4V. Some important concepts to remember are:

- Hot isostatic pressing may be required to close casting porosity.
- Heat treatment to develop properties may require close monitoring.
- Cast component properties will tend to fall in the lower end of the scatterband for wrought versions of the alloy chosen (Ti-6Al-4V, unlikely that any other conventional alloy will be cast).
- Section thickness may affect properties generated in castings.

#### 6.5 Machining and Residual Stresses

Machining of titanium alloys is similar to but more difficult than that of machining stainless steels. In welding or machining of titanium alloys, the effects

of the energy input (heat energy, deformation energy) on the microstructure and properties of the final product must be considered, just as it must be done in forging. Favorable residual stresses have been generated on titanium surfaces for years. Properties measured will degrade dramatically if the favorable surface residual stresses are reduced, for example, by chemical polishing. Shot peening is a favorite method of increasing a titanium alloy's fatigue strength, at least in airfoil roots and other nongas path regions.

## 6.6 Joining

Components of titanium alloys are routinely welded. Titanium and most titanium alloys can be joined by the following fusion welding techniques:

- Gas–tungsten arc welding (GTAW)
- Gas–metal arc welding (GMAW)
- Plasma arc welding (PAW)
- Electron beam welding (EBW)
- Laser beam welding (LBW)

and by brazing or such solid-state joining techniques as diffusion bonding, inertia bonding, and friction welding.

Just as occurs in the heat treatment of titanium and its alloys, fusion welding processes can lead to pickup of detrimental gases. Alloys must be welded in such a way as to preclude interstitial gases such as oxygen from being incorporated in the weld or weld-heat-affected area. For successful arc welding of titanium and titanium alloys, complete shielding of the weld is necessary because of the high reactivity of titanium to oxygen and nitrogen at welding temperatures. Excellent welds can be obtained in titanium and its alloys in a welding chamber, where welding is done in a protective gas atmosphere, thus giving adequate shielding. When welding titanium and titanium alloys, only argon or helium, and occasionally a mixture of these two gases, are used for shielding. Since it is more readily available and less costly, argon is more widely used. Welding in a chamber, however, is not always practical. Open-air techniques can be used with fusion welding when the area to be joined is well shielded by an inert gas using a Mylar bag for gas containment. Such atmospheric control by means of a temporary bag, or chamber, is preferred. Because titanium alloy welds are commonly used in fatigue-critical applications, a stress relief operation is generally required following welding to minimize potentially detrimental residual stresses. The essence of joining titanium and its alloys is adhering to the following principle conditions that need to be met:

- Detrimental interstitial elements must be excluded from the joint region.
- Contaminants (scale, oil, etc.) must be excluded from the joint region.
- Detrimental phase changes must be avoided to maintain joint ductility.

When proper techniques are developed and followed, the welding of thin-to-moderate section thickness in titanium alloys can be accomplished successfully using all of the aforementioned processes. For welding titanium thicker than about 2.54 mm (0.10 in.) by the GTAW process, a filler metal must be used.

For PAW, a filler metal may or may not be used for welding metal less than 12.7 mm (0.5 in.) thick.

Titanium and its alloys can be brazed. Argon, helium, and vacuum atmospheres are satisfactory for brazing titanium. For torch brazing, special fluxes must be used on the titanium. Fluxes for titanium are primarily mixtures of fluorides and chlorides of the alkali metals, sodium, potassium, and lithium. Vacuum and inert-gas atmospheres protect titanium during furnace and induction-brazing operations. Titanium assemblies frequently are brazed in high-vacuum, cold-wall furnaces. A vacuum of  $10^{-3}$  torr, or more, is required to braze titanium. Ideally, brazing should be done in a vacuum at a pressure of about  $10^{-5}$ – $10^{-4}$  torr or done in a dry inert-gas atmosphere if vacuum brazing is not possible.

## 7 OTHER ASPECTS OF TITANIUM ALLOY SELECTION

### 7.1 Corrosion

Although titanium and its alloys are used chiefly for their desirable mechanical properties, among which the most notable is their high strength-to-weight ratio, another important characteristic of the metal and its alloys is titanium's outstanding resistance to corrosion. CP titanium offers excellent corrosion resistance in most environments, except those media that contain fluoride ions. Unalloyed titanium is highly resistant to the corrosion normally associated with many natural environments, including seawater, body fluids, and fruit and vegetable juices. Titanium exposed continuously to seawater for about 18 years has undergone only superficial discoloration. Titanium is more corrosion resistant than stainless steel in many industrial environments, and its use in the chemical process industry has been continually increasing. Titanium exhibits excellent resistance to atmospheric corrosion in both marine and industrial environments.

The major corrosion problems with titanium alloys appear to be crevice corrosion, which occurs in locations where the corroding media are virtually stagnant. Pits, if formed, may progress in a similar manner. Other problem areas are with a potential for stress-corrosion, particularly at high temperatures, resulting in hot-salt stress-corrosion cracking (HSSCC). HSSCC has been observed in experimental testing and an occasional service failure. Stress-corrosion cracking (SCC) is a fracture, or cracking, phenomenon caused by the combined action of tensile stress, a susceptible alloy, and a specific corrosive environment. Another important characteristic of SCC is the requirement that tensile stress be present. Aluminum additions increase susceptibility to SCC; alloys containing more than 6% Al generally are susceptible to stress-corrosion.

HSSCC of titanium alloys is a function of temperature, stress, and time of exposure. In general, HSSCC has not been encountered at temperatures below about 260°C (500°F). The greatest susceptibility occurs at about 290–425°C (about 550–800°F) based on laboratory tests. Time-to-failure decreases as either temperature or stress level is increased. All commercial alloys, but not unalloyed titanium, have some degree of susceptibility to HSSCC. Alpha alloys are more susceptible than other alloys.

### 7.2 Biomedical Applications

Titanium alloys have become standards in the orthopedic industry where hip implants, for example, benefit from several characteristics of titanium:

- Excellent resistance to corrosion by body fluids
- High specific strength owing to good mechanical strengths and low density
- Modulus about 50–60% of that of competing cobalt-base superalloys

Corrosion resistance benefits would seem to be evident. High specific strength, however, enables a lighter implant to be made with attendant improvement in patient response to the device. Lastly, the modulus of bone is very low, about 10% of that of stainless steel or cobalt-base alloys. The degree of load transfer from the implant to the bony structure in which it is implanted and which it replaces is a direct function of the modulus. By reducing the elastic modulus, the bone can be made to receive a greater share of the load. The result with lower modulus titanium alloys is a longer operating time before breakdown of the implant–bone assembly.

### 7.3 Cryogenic Applications

Many of the available  $\alpha$  and  $\alpha$ – $\beta$  titanium alloys have been evaluated at subzero temperatures, but service experience at such temperatures has been gained only for a few alloys. Ti–5Al–2.5Sn and Ti–6Al–4V have very high strength–to–weight ratios at cryogenic temperatures and have been the preferred alloys for special applications at temperatures from  $-196$  to  $-269^{\circ}\text{C}$  ( $-320$  to  $-452^{\circ}\text{F}$ ). Impurities such as iron and the interstitials oxygen, carbon, nitrogen, and hydrogen tend to reduce the toughness of these alloys at both room and subzero temperatures. For maximum toughness, extra-low-interstitial (ELI) grades are specified for critical applications.

## 8 FINAL COMMENTS

Many titanium alloys have been developed, although the total is small compared to other metals such as steels and superalloys. A principle reason for this situation is the high cost of alloy development and of proving the worth and safety of a new material. In the sport world, titanium made a brief fling at commercial nongas turbine applications when the golf club market virtually tied up titanium metal for a short time in the 1990s. Titanium bicycle frames are marketed but are quite expensive.

The titanium market has been a roller coaster over the years, and gas turbine applications remain the most significant part of the application market. Within most aircraft gas turbine engine companies, only a few alloys have ever made it to production. Admittedly this list differs from company to company in the United States and somewhat more with alloys used outside the United States. Nevertheless, it is apparent that, although the ability to push titanium's operating environment higher in temperature has resulted in significant gains, advances have tapered off. Since the mid-1950s when Pratt & Whitney put the first titanium in U.S. gas turbines, much industrial and government funding has been used to increase alloy capabilities. Titanium aluminides have been the subject of multidecades of study with interesting but hardly commercially viable results. Barring discovery of some unforeseen nature, the message is that, if an existing alloy works and a new alloy does not offer some benefit that overrides the development cost of proving up the alloy for its new use, do not change alloys. For the ever-shrinking cadre of developers in industry, the current status suggests

that efforts to tailor existing alloys and “sell” them for new or existing applications may have better return on investment.

If an alloy selector is starting from scratch to pick an alloy for an application, then any commercially available alloy may be fair game. On the other hand, the best alloy may not be available owing to corporate patent protection or insufficient market to warrant its continued production by the limited number of manufacturers. Then, selection of another alloy from a producer may be necessary but may possibly require development costs to get the product in workable form and to determine design properties. If possible, select a known alloy that has more than one supplier and more than one casting or forging source. In all likelihood, unless a special need (such as formability of sheet) or maximum high-temperature strength is required, Ti-6Al-4V might be the first choice. For special needs such as in marine applications or biomedical orthopedic situations, choice of other alloys may be warranted. In any event, one should work with the suppliers and others in the manufacturing chain to acquire typical or design properties for the alloy in the form it will be used. Generic alloys owned by melters or developers are best for the alloy selector not associated with one of the big corporate users of titanium alloys. Companies with proprietary interests usually have nothing to benefit from giving up a technological advantage by sharing design data or even granting a production release to use a proprietary alloy. Table 11 lists a few organizations chartered to provide assistance to users of titanium products. A list of suppliers should be available from them.

### 1 INTRODUCTION

Nickel, the 24th element in abundance, has an average content of 0.016% in the outer 10 miles of the earth's crust. This is greater than the total for copper, zinc, and lead. However, few of these deposits scattered throughout the world are of commercial importance. Oxide ores commonly called laterites are largely distributed in the tropics. The igneous rocks contain high magnesium contents and have been concentrated by weathering. Of the total known ore deposits, more than 80% is contained in laterite ores. The sulfide ores found in the northern hemispheres do not easily concentrate by weathering. The sulfide ores in the Sudbury district of Ontario, which contain important by-products such as copper, cobalt, iron, and precious metals are the world's greatest single source of nickel.<sup>1</sup>

Nickel has an atomic number of 28 and is one of the transition elements in the fourth series in the periodic table. The atomic weight is 58.71 and density is 8.902 g/cm<sup>3</sup>. Useful properties of the element are the modulus of elasticity and its magnetic and magnetostrictive properties, and high thermal and electrical conductivity. Hydrogen is readily adsorbed on the surface of nickel. Nickel will also adsorb other gases such as carbon monoxide, carbon dioxide, and ethylene. It is this capability of surface adsorption of certain gases without forming stable compounds that makes nickel an important catalyst.<sup>2</sup>

As an alloying element, nickel is used in hardenable steels, stainless steels, special corrosion-resistant and high-temperature alloys, copper–nickel, “nickel–silvers,” and aluminum–nickel. Nickel imparts ductility and toughness to cast iron.

Approximately 10% of the total annual production of nickel is consumed by electroplating processes. Nickel can be electrodeposited to develop mechanical properties of the same order as wrought nickel; however, special plating baths are available that will yield nickel deposits possessing a hardness as high as 450 Vickers (425 BHN). The most extensive use of nickel plate is for corrosion protection of iron and steel parts and zinc-base die castings used in the automotive field. For these applications, a layer of nickel, 0.0015–0.003 in. thick, is used. This nickel plate is then finished or covered with a chromium plate consisting in thickness of about 1% of the underlying nickel plate thickness in order to maintain a brilliant, tarnish-free, hard exterior surface.

## 2 NICKEL ALLOYS

Most of the alloys listed and discussed are in commercial production. However, producers from time to time introduce improved modifications that make previous alloys obsolete. For this reason, or economic reasons, they may remove certain alloys from their commercial product line. Some of these alloys have been included to show how a particular composition compares with the strength or corrosion resistance of currently produced commercial alloys.

### 2.1 Classification of Alloys

Nickel and its alloys can be classified into the following groups on the basis of chemical composition.<sup>3</sup>

#### Nickel

(1) Pure nickel, electrolytic (99.56% Ni), carbonyl nickel powder and pellet (99.95% Ni); (2) commercially pure wrought nickel (99.6–99.97% nickel); and (3) anodes (99.3% Ni).

#### Nickel and Copper

(1) Low-nickel alloys (2–13% Ni); (2) cupronickels (10–30% Ni); (3) coinage alloy (25% Ni); (4) electrical resistance alloy (45% Ni); (5) nonmagnetic alloys (up to 60% Ni); and (6) high-nickel alloys, Monel (over 50% Ni).

#### Nickel and Iron

Wrought alloy steels (0.5–9% Ni); (2) cast alloy steels (0.5–9% Ni); (3) alloy cast irons (1–6 and 14–36% Ni); (4) magnetic alloys (20–90% Ni): (a) controlled coefficient of expansion (COE) alloys (29.5–32.5% Ni) and (b) high-permeability alloys (49–80% Ni); (5) nonmagnetic alloys (10–20% Ni); (6) clad steels (5–40% Ni); (7) thermal expansion alloys: (a) low expansion (36–50% Ni) and (b) selected expansion (22–50% Ni).

#### Iron, Nickel, and Chromium

(1) Heat-resisting alloys (40–85% Ni); (2) electrical resistance alloys (35–60% Ni); (3) iron-base superalloys (9–26% Ni); (4) stainless steels (2–25% Ni); (5) valve steels (2–13% Ni); (6) iron-base superalloys (0.2–9% Ni); (7) maraging steels (18% Ni).

### **Nickel, Chromium, Molybdenum, and Iron**

(1) Nickel-base solution-strengthened alloys (40–70% Ni); (2) nickel-base precipitation-strengthened alloys (40–80% Ni).

### **Powder-Metallurgy Alloys**

(1) Nickel-base dispersion strengthened (78–98% Ni); (2) nickel-base mechanically alloyed oxide-dispersion-strengthened (ODS) alloys (69–80% Ni).

The nominal chemical composition of nickel-base alloys is given in Table 1. This table does not include alloys with less than 30% Ni, cast alloys, or welding products. For these and those alloys not listed, the chemical composition and applicable specifications can be found in the *Unified Numbering System for Metals and Alloys*, published by the Society of Automotive Engineers, Inc.

## **2.2 Discussion and Applications**

The same grouping of alloys used in Tables 1, 2, and 3, which give chemical composition and mechanical properties, will be used for discussion of the various attributes and uses of the alloys as a group. Many of the alloy designations are registered trademarks of producer companies.

### **Nickel Alloys**

The corrosion resistance of nickel makes it particularly useful for maintaining product purity in the handling of foods, synthetic fibers, and caustic alkalies, and also in structural applications where resistance to corrosion is a prime consideration. It is a general-purpose material used when the special properties of the other nickel alloys are not required. Other useful features of the alloy are its magnetic and magnetostrictive properties; high thermal and electrical conductivity; low gas content; and low vapor pressure.<sup>4</sup>

Typical *nickel 200* applications are food-processing equipment, chemical shipping drums, electrical and electronic parts, aerospace and missile components, caustic handling equipment and piping, and transducers.

*Nickel 201* is preferred to nickel 200 for applications involving exposure to temperatures above 316°C (600°F). Nickel 201 is used as coinage, plater bars, and combustion boats in addition to some of the applications for Nickel 200.

*Permanickel alloy 300* by virtue of the magnesium content is age-hardenable. But, because of its low alloy content, alloy 300 retains many of the characteristics of nickel. Typical applications are grid lateral winding wires, magnetostriction devices, thermostat contact arms, solid-state capacitors, grid side rods, diaphragms, springs, clips, and fuel cells.

*Duranickel alloy 301* is another age-hardenable high nickel alloy, but is made heat treatable by aluminum and titanium additions. The important features of alloy 301 are high strength and hardness, good corrosion resistance, and good spring properties up to 316°C (600°F); and it is on these mechanical considerations that selection of the alloy is usually based. Typical applications are extrusion press parts, molds used in the glass industry, clips, diaphragms, and springs.

### **Nickel–Copper Alloys**

Nickel–copper alloys are characterized by high strength, weldability, excellent corrosion resistance, and toughness over a wide temperature range. They have

Table 1 Nominal Chemical Composition (wt%)

<sup>a</sup>MPa ksi × 6.895.

excellent service in seawater or brackish water under high-velocity conditions, as in propellers, propeller shafts, pump shafts, and impellers and condenser tubes, where resistance to the effects of cavitation and erosion are important. Corrosion rates in strongly agitated and aerated seawater usually do not exceed 1 mil/year.

*Monel alloy 400* has low corrosion rates in chlorinated solvents, glass-etching agents, sulfuric and many other acids, and practically all alkalis, and it is resistant to stress-corrosion cracking. Alloy 400 is useful up to 538°C (1000°F) in oxidizing atmospheres, and even higher temperatures may be used if the environment is reducing. Springs of this material are used in corrosive environments up to 232°C (450°F). Typical applications are valves and pumps; pump and propeller shafts; marine fixtures and fasteners; electrical and electronic components; chemical processing equipment; gasoline and freshwater tanks; crude petroleum stills, process vessels, and piping; boiler feedwater heaters and other heat exchangers; and deaerating heaters.

*Monel alloy 404* is characterized by low magnetic permeability and excellent brazing characteristics. Residual elements are controlled at low levels to provide

a clean, wettable surface even after prolonged firing in wet hydrogen. Alloy 404 has a low Curie temperature and its magnetic properties are not appreciably affected by processing or fabrication. This magnetic stability makes alloy 404 particularly suitable for electronic applications. Much of the strength of alloy 404 is retained at outgassing temperatures. Thermal expansion of alloy 404 is sufficiently close to that of many other alloys as to permit the firing of composite metal tubes with negligible distortion. Typical applications are waveguides, metal-to-ceramic seals, transistor capsules, and power tubes.

*Monel alloy R-405* is a free-machining material intended almost exclusively for use as stock for automatic screw machines. It is similar to alloy 400 except that a controlled amount of sulfur is added for improved machining characteristics. The corrosion resistance of alloy R-405 is essentially the same as that of alloy 400, but the range of mechanical properties differs slightly. Typical applications are water meter parts, screw machine products, fasteners for nuclear applications, and valve seat inserts.

*Monel alloy K-500* is an age-hardenable alloy that combines the excellent corrosion resistance characteristics of the Monel nickel-copper alloys with the added advantage of increased strength and hardness. Age hardening increases its strength and hardness. Still better properties are achieved when the alloy is cold-worked prior to the aging treatment. Alloy K-500 has good mechanical properties over a wide temperature range. Strength is maintained up to about 649°C (1200°F), and the alloy is strong, tough, and ductile at temperatures as low as -253°C (-423°F). It also has low permeability and is nonmagnetic to -134°C (-210°F). Alloy K-500 has low corrosion rates in a wide variety of environments. Typical applications are pump shafts and impellers, doctor blades and scrapers, oil-well drill collars and instruments, electronic components, and springs.

### **Nickel-Chromium-Iron Alloys**

This family of alloys was developed for high-temperature oxidizing environments. These alloys typically contain 50–80% nickel, which permits the addition of other alloying elements to improve strength and corrosion resistance while maintaining toughness.

*Inconel alloy 600* is a standard engineering material for use in severely corrosive environments at elevated temperatures. It is resistant to oxidation at temperatures up to 1177°C (2150°F). In addition to corrosion and oxidation resistance, alloy 600 presents a desirable combination of high strength and workability, and is hardened and strengthened by cold-working. This alloy maintains strength, ductility, and toughness at cryogenic as well as elevated temperatures. Because of its resistance to chloride-ion stress-corrosion cracking and corrosion by high-purity water, it is used in nuclear reactors. For this service, the alloy is produced to exacting specifications and is designated Inconel alloy 600T. Typical applications are furnace muffles, electronic components, heat-exchanger tubing, chemical- and food-processing equipment, carburizing baskets, fixtures and rotors, reactor control rods, nuclear reactor components, primary heat-exchanger tubing, springs, and primary water piping. Alloy 600, being one of the early high-temperature, corrosion-resistant alloys, can be thought of as being the basis of many of our present day special-purpose high-nickel alloys, as illustrated in Fig. 1.

**Fig. 1** Some compositional modifications of nickel and its alloys to produce special properties.

*Inconel alloy 601* has shown very low rates of oxidation and scaling at temperatures as high as 1093°C (2000°F). The high chromium content (nominally 23%) gives alloy 601 resistance to oxidizing, carburizing, and sulfur-containing environments. Oxidation resistance is further enhanced by the aluminum content. Typical applications are heat-treating baskets and fixtures, radiant furnace tubes, strand-annealing tubes, thermocouple protection tubes, and furnace muffles and retorts.

*Inconel alloy 690* is a high-chromium nickel alloy having very low corrosion rates in many corrosive aqueous media and high-temperature atmospheres. In various types of high-temperature water, alloy 690 also displays low corrosion rates and excellent resistance to stress-corrosion cracking—desirable attributes

for nuclear steam-generator tubing. In addition, the alloy's resistance to sulfur-containing gases makes it a useful material for such applications as coal-gasification units, burners and ducts for processing sulfuric acid, furnaces for petrochemical processing, and recuperators and incinerators.

*Inconel alloy 706* is a precipitation-hardenable alloy with characteristics similar to alloy 718, except that alloy 706 has considerably improved machinability. It also has good resistance to oxidation and corrosion over a broad range of temperatures and environments. Like alloy 718, alloy 706 has excellent resistance to postweld strain-age cracking. Typical applications are gas-turbine components and other parts that must have high strength combined with good machinability and weldability.

*Inconel alloy 718* is an age-hardenable high-strength alloy suitable for service at temperatures from  $-253^{\circ}\text{C}$  ( $-423^{\circ}\text{F}$ ) to  $704^{\circ}\text{C}$  ( $1300^{\circ}\text{F}$ ). The fatigue strength of alloy 718 is high, and the alloy exhibits high stress-rupture strength up to  $704^{\circ}\text{C}$  ( $1300^{\circ}\text{F}$ ) as well as oxidation resistance up to  $982^{\circ}\text{C}$  ( $1800^{\circ}\text{F}$ ). It also offers good corrosion resistance to a wide variety of environments. The outstanding characteristic of alloy 718 is its slow response to age hardening. The slow response enables the material to be welded and annealed with no spontaneous hardening unless it is cooled slowly. Alloy 718 can also be repair-welded in the fully aged condition. Typical applications are jet engine components, pump bodies and parts, rocket motors and thrust reversers, and spacecraft.

*Inconel alloy X-750* is an age-hardenable nickel–chromium–iron alloy used for its corrosion and oxidation resistance and high creep-rupture strength up to  $816^{\circ}\text{C}$  ( $1500^{\circ}\text{F}$ ). The alloy is made age-hardenable by the addition of aluminum, columbium, and titanium, which combine with nickel, during proper heat treatment, to form the intermetallic compound  $\text{Ni}_3(\text{Al}, \text{Ti})$ . Alloy X-750, originally developed for gas turbines and jet engines, has been adopted for a wide variety of other uses because of its favorable combination of properties. Excellent relaxation resistance makes alloy X-750 suitable for springs operating at temperatures up to about  $649^{\circ}\text{C}$  ( $1200^{\circ}\text{F}$ ). The material also exhibits good strength and ductility at temperatures as low as  $-253^{\circ}\text{C}$  ( $-423^{\circ}\text{F}$ ). Alloy X-750 also exhibits high resistance to chloride-ion stress-corrosion cracking even in the fully age-hardened condition. Typical applications are gas-turbine parts (aviation and industrial), springs (steam service), nuclear reactors, bolts, vacuum envelopes, heat-treating fixtures, extrusion dies, aircraft sheet, bellows, and forming tools.

### **Nickel–Iron–Chromium Alloys**

This series of alloys typically contains 30–45% Ni and is used in elevated- or high-temperature environments where resistance to oxidation or corrosion is required.

*Incoloy alloy 800* is a widely used material of construction for equipment that must resist corrosion, have high strength, or resist oxidation and carburization. The chromium in the alloy imparts resistance to high-temperature oxidation and general corrosion. Nickel maintains an austenitic structure so that the alloy remains ductile after elevated-temperature exposure. The nickel content also contributes resistance to scaling, general corrosion, and stress-corrosion cracking. Typical applications are heat-treating equipment and heat exchangers in the chemical, petrochemical, and nuclear industries, especially where resis-

tance to stress-corrosion cracking is required. Considerable quantities are used for sheathing on electric heating elements.

*Incoloy alloy 800H* is a version of Incoloy alloy 800 having significantly higher creep and rupture strength. The two alloys have the same chemical composition with the exception that the carbon content of alloy 800H is restricted to the upper portion of the standard range for alloy 800. In addition to a controlled carbon content, alloy 800H receives an annealing treatment that produces a coarse grain size—an ASTM number of 5 or coarser. The annealing treatment and carbon content are responsible for the alloy's greater creep and rupture strength.

Alloy 800H is useful for many applications involving long-term exposure to elevated temperatures or corrosive atmospheres. In chemical and petrochemical processing, the alloy is used in steam/hydrocarbon reforming for catalyst tubing, convection tubing, pigtails, outlet manifolds, quenching-system piping, and transfer piping; in ethylene production for both convection and cracking tubes; in oxo-alcohol production for tubing in hydrogenation heaters; in hydrodealkylation units for heater tubing; and in production of vinyl chloride monomer for cracking tubes, return bends, and inlet and outlet flanges.

Industrial heating is another area of wide usage for alloy 800H. In various types of heat-treating furnaces, the alloy is used for radiant tubes, muffles, retorts, and assorted furnace fixtures. Alloy 800H is also used in power generation for steam superheater tubing and high-temperature heat exchangers in gas-cooled nuclear reactors.

*Incoloy alloy 825* was developed for use in aggressively corrosive environments. The nickel content of the alloy is sufficient to make it resistant to chloride-ion stress-corrosion cracking, and, with molybdenum and copper, alloy 825 has resistance to reducing acids. Chromium confers resistance to oxidizing chemicals. The alloy also resists pitting and intergranular attack when heated in the critical sensitization temperature range. Alloy 825 offers exceptional resistance to corrosion by sulfuric acid solutions, phosphoric acid solutions, and seawater. Typical applications are phosphoric acid evaporators, pickling-tank heaters, pickling hooks and equipment, chemical-process equipment, spent nuclear fuel element recovery, propeller shafts, tank trucks, and oil-country cold-worked tubulars.

*Incoloy alloy 925* was developed for severe conditions found in corrosive wells containing  $\text{H}_2\text{S}$ ,  $\text{CO}_2$ , and brine at high pressures. Alloy 925 is a weldable, age-hardenable alloy having corrosion and stress-corrosion resistance similar to Incoloy alloy 825. It is recommended for applications where alloy 825 does not have adequate yield or tensile strength for service in the production of oil and gas, such as valve bodies, hanger bars, flow lines, casing, and other tools and equipment.

*Pyromet 860* and *Refractaloy 26* are high-temperature precipitation-hardenable alloys with lower nickel content than Inconel alloy X-750 but with additions of cobalt and molybdenum. The precipitation-hardening elements are the same except the Al/Ti ratio is reversed with titanium content being greater than aluminum. Typical applications of both alloys are critical components of gas turbines, bolts, and structural members.<sup>8</sup>

## Nickel–Iron

The nickel–iron alloys listed in Table 1 as a group have a low coefficient of expansion that remains virtually constant to a temperature below the Curie temperature for each alloy. A major application for *Nilo alloy 36* is tooling for curing composite airframe components. The thermal expansion characteristics of *Nilo alloy 42* are particularly useful for semiconductor lead frames and glass-sealing applications.

*Ni-Span-C alloy 902* and *Incoloy alloys 903 and 907* are precipitation-hardenable alloys with similar thermal expansion characteristics to *Nilo alloy 42* but having different constant coefficient of expansion temperature range. Alloy 902 is frequently used in precision apparatus where elastic members must maintain a constant frequency when subjected to temperature fluctuations. Alloys 903 and 907 are being used in aircraft jet engines for members requiring high-temperature strengths to 649°C (1200°F) with thermal expansion controlled to maintain low clearance.

## Nickel–Chromium–Molybdenum Alloys

This group of alloys contains 45–60% Ni and was developed for severe corrosion environments. Many of these alloys also have good oxidation resistance and some have useful strength to 1093°C (2000°F).

*Hastelloy alloy X* is a non-age-hardenable nickel–chromium–iron–molybdenum alloy developed for high-temperature service up to 1204°C (2200°F). Typical applications are furnace hardware subjected to oxidizing, reducing, and neutral atmospheres; aircraft jet engine tail pipes; and combustion cans and afterburner components.<sup>5,6</sup>

*Hastelloy alloy C* is a mildly age-hardenable alloy similar in composition to alloy X except nearly all the iron is replaced with molybdenum and nickel. It is highly resistant to strongly oxidizing acids, salts, and chlorine. It has good high-temperature strength. Typical applications are chemical, petrochemical, and oil refinery equipment; aircraft jet engines; and heat-treating equipment.<sup>6,7</sup>

*Hastelloy alloy C-276* is a modification of *Hastelloy alloy C* where the carbon and silicon content is reduced to very low levels to diminish carbide precipitation in the heat-affected zone of weldments. Alloy C-276 is non-age-hardenable and is used in the solution-treated condition. No postwelding heat treatment is necessary for chemical-process equipment. Typical applications are chemical- and petro-chemical-process equipment, aircraft jet engines, and deep sour gas wells.<sup>6,7</sup>

*Hastelloy alloy G* is a non-age-hardenable alloy similar to the composition of alloy X but with 2% copper and 2% columbium and lower carbon content. Alloy G is resistant to pitting and stress-corrosion cracking. Typical applications are paper and pulp equipment, phosphate fertilizer, and synthetic fiber processing.<sup>6,7</sup>

*Inconel alloy 617* is a solid-solution-strengthened alloy containing cobalt that has an exceptional combination of high-temperature strength and oxidation resistance which makes alloy 617 a useful material for gas-turbine aircraft engines and other applications involving exposure to extreme temperatures, such as, steam generator tubing and pressure vessels for advanced high-temperature gas-cooled nuclear reactors.

*Inconel alloy 625*, like alloy 617, is a solid-solution-strengthened alloy but containing columbium instead of cobalt. This combination of elements is responsible for superior resistance to a wide range of corrosive environments of unusual severity as well as to high-temperature effects such as oxidation and carburization. The properties of alloy 625 that make it attractive for seawater applications are freedom from pitting and crevice corrosion, high corrosion fatigue strength, high tensile strength, and resistance to chloride-ion stress-corrosion cracking. Typical applications are wire rope for mooring cables; propeller blades; submarine propeller sleeves and seals; submarine snorkel tubes; aircraft ducting, exhausts, thrust-reverser, and spray bars; and power plant scrubbers, stack liners, and bellows.

*MAR-M-252*, *Rene' 41*, *Rene' 95*, and *Astroloy* are a group of age-hardenable nickel-base alloys containing 10–15% cobalt designed for highly stressed parts operating at temperatures from 871 to 982°C (1600 to 1800°F) in jet engines. *MAR-M-252* and *Rene' 41* have nearly the same composition but *Rene' 41* contains more of the age-hardening elements allowing higher strengths to be obtained. *Rene' 95*, of similar base composition but in addition containing 3.5% columbium and 3.5% tungsten, is used at temperatures between 371 and 649°C (700 and 1200°F). Its primary use is as disks, shaft retaining rings, and other rotating parts in aircraft engines of various types.<sup>6–8</sup>

*Udimet 500*, *520*, *600*, and *700* and *Unitemp 1753* are age-hardenable, nickel-base alloys having high strength at temperatures up to 982°C (1800°F). All contain a significant amount of cobalt. Applications include jet engine gas-turbine blades, combustion chambers, rotor disks, and other high-temperature components.<sup>6–8</sup>

*Waspaloy* is an age-hardenable nickel-base alloy developed to have high strength up to 760°C (1400°F) combined with oxidation resistance to 871°C (1600°F). Applications are jet engine turbine buckets and disks, air frame assemblies, missile systems, and high-temperature bolts and fasteners.<sup>6–8</sup>

### **Nickel Powder Alloys (Dispersion Strengthened)**

These oxide dispersion strengthened (ODS) alloys are produced by a proprietary powder metallurgical process using thoria as the dispersoid. The mechanical properties to a large extent are determined by the processing history. The preferred thermomechanical processing results in an oriented texture with grain aspect ratios of about 3:1 to 6:1.

*TD-nickel* and *TD-NiCr* are dispersion-hardened nickel alloys developing useful strengths up to 1204°C (2200°F). These alloys are difficult to fusion weld without reducing the high-temperature strength. Brazing is used in the manufacture of jet engine hardware. Applications are jet engine parts, rocket nozzles, and afterburner liners.<sup>6–8</sup>

### **Nickel Powder Alloys (Mechanically Alloyed)**

*Inconel alloy MA 754* and *Inconel alloy MA 6000* are ODS nickel-base alloys produced by mechanical alloying.<sup>9,10</sup> An yttrium oxide dispersoid imparts high creep-rupture strength up to 1149°C (2100°F). *MA 6000* is also age-hardenable, which increases strength at low temperatures up to 760°C (1400°F). These mechanical alloys like the thoria-strengthened alloys described are difficult to fusion

weld without reducing high-temperature strength. Useful strength is obtained by brazing. MA 754 is being used as aircraft gas-turbine vanes and bands. Applications for MA 6000 are aircraft gas turbine buckets and test grips.

### 3 CORROSION

It is well recognized that the potential saving is very great by utilizing available and economic practices to improve corrosion prevention and control. Not only should the designer consider initial cost of materials, but he or she should also include the cost of maintenance, length of service, downtime cost, and replacement costs. This type of cost analysis can frequently show that more highly alloyed, corrosion-resistant materials are more cost effective. The National Commission on Materials Policy concluded that one of the "most obvious opportunities for material economy is control of corrosion."

Studies have shown that the total cost of corrosion is astonishing. The overall cost of corrosion in the United States was estimated by the National Bureau of Standards in 1978 and updated by Battelle scientists in 1995. According to a report released in April, metallic corrosion costs the United States about \$300 billion a year. The report, released by Battelle (Columbus, Ohio) and Specialty Steel Industry of North America (SSINA, Washington, DC), claims that about one-third of the costs of corrosion (\$100 billion) is avoidable and could be saved by broader use of corrosion-resistant materials and the application of best anti-corrosion technology from design through maintenance.

Since becoming commercially available shortly after the turn of the century, nickel has become very important in combating corrosion. It is a major constituent in the plated coatings and claddings applied to steel, corrosion-resistant stainless steels, copper–nickel and nickel–copper alloys, high-nickel alloys, and commercially pure nickel alloys. Not only is nickel a corrosion-resistant element in its own right, but, owing to its high tolerance for alloying, it has been possible to develop many metallurgically stable, special-purpose alloys.<sup>11</sup>

Figure 1 shows the relationship of these alloys and the major effect of alloying elements. Alloy 600 with 15% chromium, one of the earliest of the nickel–chromium alloys, can be thought of as the base for other alloys. Chromium imparts resistance to oxidizing environments and high-temperature strength. Increasing chromium to 30%, as in alloy 690, increases resistance to stress-corrosion cracking, nitric acid, steam, and oxidizing gases. Increasing chromium to 50% increases resistance to melting sulfates and vanadates found in fuel ash. High-temperature oxidation resistance is also improved by alloying with aluminum in conjunction with high chromium (e.g., alloy 601).

Without chromium, nickel by itself is used as a corrosion-resistant material in food processing and in high-temperature caustic and gaseous chlorine or chloride environments.

Of importance for aqueous reducing acids, oxidizing chloride environments, and seawater are alloy 625 and alloy C-276, which contain 9% and 16% molybdenum, respectively, and are among the most resistant alloys currently available. Low-level titanium and aluminum additions provide  $\gamma'$  strengthening while retaining good corrosion resistance, as in alloy X-750. Cobalt and other alloying element additions provide jet engine materials (superalloys) that combine high-temperature strength with resistance to gaseous oxidation and sulfidation.

Another technologically important group of materials are the higher-iron alloys, which were originally developed to conserve nickel and are often regarded as intermediate in performance and cost between nickel alloys and stainless steels. The prototype, alloy 800 (Fe/33% Ni/21% Cr), is a general purpose alloy with good high-temperature strength and resistance to steam and oxidizing or carburizing gases. Alloying with molybdenum and chromium, as in alloy 825 and alloy G, improves resistance to reducing acids and localized corrosion in chlorides.

Another important category is the nickel–copper alloys. At the higher-nickel end are the Monel alloys (30–45% Cu, balance Ni) used for corrosive chemicals such as hydrofluoric acid, and severe marine environments. At the higher-copper end are the cupronickels (10–30% Ni, balance Cu), which are widely used for marine applications because of their fouling resistance.

Nickel alloys exhibit high resistance to attack under nitriding conditions (e.g., in dissociated ammonia) and in chlorine or chloride gases. Corrosion in the latter at elevated temperatures proceeds by the formation and volatilization of chloride scales, and high-nickel contents are beneficial since nickel forms one of the least volatile chlorides. Conversely, in sulfidizing environments, high-nickel alloys without chromium can exhibit attack due to the formation of a low-melting-point Ni–Ni<sub>3</sub>Si<sub>2</sub> eutectic. However high chromium contents appear to limit this form of attack.<sup>5</sup>

Friend explains corrosion reactions as wet or dry:<sup>11</sup>

*The term wet corrosion usually refers to all forms of corrosive attack by aqueous solutions of electrolytes, which can range from pure water (a weak electrolyte) to aqueous solutions of acids or bases or of their salts, including neutral salts. It also includes natural environments such as the atmosphere, natural waters, soils, and others, irrespective of whether the metal is in contact with a condensed film or droplets of moisture or is completely immersed. Corrosion by aqueous environments is electrochemical in nature, assuming the presence of anodic and cathodic areas on the surface of the metal even though these areas may be so small as to be indistinguishable by experimental methods and the distance between them may be only of atomic dimensions.*

*The term dry corrosion implies the absence of water or an aqueous solution. It generally is applied to metal/gas or metal/vapor reactions involving gases such as oxygen, halogens, hydrogen sulfide, and sulfur vapor and even to “dry” steam at elevated temperatures. . . . High-temperature oxidation of metals has been considered to be an electrochemical phenomenon since it involves the diffusion of metal ions outward, or of reactant ions inward, through the corrosion product film, accompanied by a flow of electrons.*

The decision to use a particular alloy in a commercial application is usually based on past corrosion experience and laboratory or field testing using test spools of candidate alloys. Most often weight loss is measured to rank various alloys; however, many service failures are due to localized attack such as pitting, crevice corrosion, intergranular corrosion, and stress-corrosion cracking, which must be measured by other means.

A number of investigations have shown the effect of nickel on the different forms of corrosion. Figure 2 shows the galvanic series of many alloys in flowing seawater. This series gives an indication of the rate of corrosion between different metals or alloys when they are electrically coupled in an electrolyte. The metal close to the active end of the chart will behave as an anode and corrode, and the metal closer to the noble end will act as a cathode and be protected.

**Fig. 2** Corrosion potentials in flowing seawater (8–13 ft/sec), temperature range 50–80°F. Alloys are listed in the order of the potential they exhibit in flowing seawater. Certain alloys, indicated by solid boxes, in low velocity or poorly aerated water, and at shielded areas, may become active and exhibit a potential near -0.5 V.

Increasing the nickel content will move an alloy more to the noble end of the series. There are galvanic series for other corrosive environments, and the film-forming characteristics of each material may change this series somewhat. Seawater is normally used as a rough guide to the relative positions of alloys in solution of good electrical conductivity such as mineral acids or salts.

Residual stresses from cold rolling or forming do not have any significant effect on the general corrosion rate. However, many low-nickel-containing steels are subject to stress-corrosion cracking in chloride-containing environments. Figure 3 from work by LaQue and Copson<sup>12</sup> shows that nickel–chromium and nickel–chromium–iron alloys containing about 45% Ni or more are immune from stress-corrosion cracking in boiling 42% magnesium chloride.<sup>11</sup>

When localized corrosion occurs in well-defined areas, such corrosion is commonly called *pitting attack*. This type of corrosion typically occurs when the protective film is broken or is penetrated by a chloride–iron and the film is unable to repair itself quickly. The addition of chromium and particularly molybdenum makes nickel–base alloys less susceptible to pitting attack, as shown in Fig. 4, which shows a very good relationship between critical<sup>11</sup> pitting temperature in a salt solution. Along with significant increases in chromium and/or

**Fig. 3** Breaking time of iron–nickel–chromium wires under tensile stress in boiling 42% magnesium chloride.

**Fig. 4** Critical temperature for pitting in 4% NaCl + 1% Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> + 0.01 M HCl versus composition for Fe–Ni–Cr–Mo alloys.

molybdenum, the iron content must be replaced with more nickel in wrought alloys to resist the formation of embrittling phases.<sup>12,13</sup>

Air oxidation at moderately high temperatures will form an intermediate sub-surface layer between the alloy and gas quickly. Alloying of the base alloy can affect this subscale oxide and, therefore, control the rate of oxidation. At constant temperature, the resistance to oxidation is largely a function of chromium content. Early work by Eiselstein and Skinner has shown that nickel content is very beneficial under cyclic temperature conditions as shown in Fig. 5.<sup>14</sup>

**4 FABRICATION**

The excellent ductility and malleability of nickel and nickel-base alloys in the annealed condition make them adaptable to virtually all methods of cold fabrication. As other engineering properties vary within this group of alloys, formability ranges from moderately easy to difficult in relation to other materials.

**4.1 Resistance to Deformation**

Resistance to deformation, usually expressed in terms of hardness or yield strength, is a primary consideration in cold forming. Deformation resistance is

**Fig. 5** Effect of nickel content on air oxidation of alloys. Each cycle consisted of 15 min at 1800°F followed by a 5-min air cooling.

moderately low for the nickel and nickel–copper systems and moderately high for the nickel–chromium and nickel–iron–chromium systems. However, when properly annealed, even the high-strength alloys have a substantial range between yield and ultimate tensile strength. This range is the plastic region of the material and all cold forming is accomplished within the limits of this region. Hence, the high-strength alloys require only stronger tooling and more powerful equipment for successful cold forming. Nominal tensile properties and hardnesses are given in Table 2.

**4.2 Strain Hardening**

A universal characteristic of the high-nickel alloys is that they have face-centered-cubic crystallographic structures, and, consequently, are subject to rapid strain hardening. This characteristic is used to advantage in increasing the room-temperature tensile properties and hardness of alloys that otherwise would have low mechanical strength, or in adding strength to those alloys that are hardened by a precipitation heat treatment. Because of this increased strength, large re-

ductions can be made without rupture of the material. However, the number of reductions in a forming sequence will be limited before annealing is required, and the percentage reduction in each successive operation must be reduced.

Since strain hardening is related to the solid-solution strengthening of alloying elements, the strain-hardening rate generally increases with the complexity of the alloy. Accordingly, strain-hardening rates range from moderately low for nickel and nickel-copper alloys to moderately high for nickel-chromium and nickel-iron-chromium alloys. Similarly, the age-hardenable alloys have higher strain-hardening rates than their solid-solution equivalents. Figure 6 compares the strain-hardening rates of some nickel alloys with those of other materials as shown by the increase in hardness with increasing cold reduction.

Laboratory tests have indicated that the shear strength of the high-nickel alloys in double shear averages about 65% of the ultimate tensile strength (see Table 4). These values, however, were obtained under essentially static conditions using laboratory testing equipment having sharp edges and controlled clearances. Shear loads for well-maintained production equipment can be found in Table 5. These data were developed on a power shear having a 31 mm/m ( $\frac{3}{8}$  in./ft) rake.

## 5 HEAT TREATMENT

High-nickel alloys are subject to surface oxidation unless heating is performed in a protective atmosphere or under vacuum. A protective atmosphere can be provided either by controlling the ratio of fuel and air to minimize oxidation or by surrounding the metal being heated with a prepared atmosphere.

Monel alloy 400, Nickel 200, and similar alloys will remain bright and free from discoloration when heated and cooled in a reducing atmosphere formed by the products of combustion. The alloys that contain chromium, aluminum, or

Fig. 6 Effect of cold work on hardness.

Table 4 Strength in Double Shear of Nickel and Nickel Alloys

| Alloy               | Condition                 | Shear Strength (ksi) <sup>a</sup> | Tensile Strength (ksi) | Hardness |
|---------------------|---------------------------|-----------------------------------|------------------------|----------|
| Nickel 200          | Annealed                  | 52                                | 68                     | 46 Rb    |
|                     | Half-hard                 | 58                                | 79                     | 84 Rb    |
|                     | Full-hard                 | 75                                | 121                    | 100 Rb   |
| Monel alloy 400     | Hot-rolled, annealed      | 48                                | 73                     | 65 Rb    |
|                     | Cold-rolled, annealed     | 49                                | 76                     | 60 Rb    |
| Inconel alloy 600   | Annealed                  | 60                                | 85                     | 71 Rb    |
|                     | Half-hard                 | 66                                | 98                     | 98 Rb    |
|                     | Full-Hard                 | 82                                | 152                    | 31 Rc    |

<sup>b</sup>Mill-annealed and aged 1300°F (750°C)/20 hr.

titanium form thin oxide films in the same atmosphere and, therefore, require prepared atmospheres to maintain bright surfaces.

Regardless of the type of atmosphere used, it must be free of sulfur. Exposure of nickel alloys to sulfur-containing atmospheres at high temperatures can cause severe sulfidation damage.

The atmosphere of concern is that in the immediate vicinity of the work, that is, the combustion gases that actually contact the surface of the metal. The true condition of the atmosphere is determined by analyzing gas samples taken at various points about the metal surface.

Furnace atmospheres can be checked for excessive sulfur by heating a small test piece of the material, for example, 13 mm (½ in.) diameter rod or 13 mm × 25 mm (½ in. × 1 in.) flat bar, to the required temperature and holding it at temperature for 10–15 min. The piece is then air cooled or water quenched and bent through 180° flat on itself. If heating conditions are correct, there will be no evidence of cracking.

<sup>a</sup>MPa = ksi × 6.895.  
<sup>b</sup>kg = lb × 0.4536.

## 5.1 Reducing Atmosphere

The most common protective atmosphere used in heating the nickel alloys is that provided by controlling the ratio between the fuel and air supplied to the burners. A suitable reducing condition can be obtained by using a slight excess of fuel so that the products of combustion contain at least 4%, preferably 6%, of carbon monoxide plus hydrogen. The atmosphere should not be permitted to alternate from reducing to oxidizing; only a slight excess of fuel over air is needed.

It is important that combustion take place before the mixture of fuel and air comes into contact with the work, otherwise the metal may be embrittled. To ensure proper combustion, ample space should be provided to burn the fuel completely before the hot gases contact the work. Direct impingement of the flame can cause cracking.

## 5.2 Prepared Atmosphere

Various prepared atmospheres can be introduced into the heating and cooling chambers of furnaces to prevent oxidation of nickel alloys. Although these atmospheres can be added to the products of combustion in a directly fired furnace, they are more commonly used with indirectly heated equipment. Prepared protective atmospheres suitable for use with the nickel alloys include dried hydrogen, dried nitrogen, dried argon or any other inert gas, dissociated ammonia, and cracked or partially reacted natural gas. For the protection of pure nickel and nickel-copper alloys, cracked natural gas should be limited to a dew point of  $-1$  to  $4^{\circ}\text{C}$  ( $30$  to  $40^{\circ}\text{F}$ ).

Figure 7 indicates that at a temperature of  $1093^{\circ}\text{C}$  ( $2000^{\circ}\text{F}$ ), a hydrogen dew point of less than  $-30^{\circ}\text{C}$  ( $-20^{\circ}\text{F}$ ) is required to reduce chromium oxide to chromium; at  $815^{\circ}\text{C}$  ( $1500^{\circ}\text{F}$ ) the dew point must be below  $-50^{\circ}\text{C}$  ( $-60^{\circ}\text{F}$ ). The values were derived from the thermodynamic relationships of pure metals with their oxides at equilibrium, and should be used only as a guide to the behavior of complex alloys under nonequilibrium conditions. However, these curves have shown a close correlation with practical experience. For example, Inconel alloy 600 and Incoloy alloy 800 are successfully bright-annealed in hydrogen having a dew point of  $-35$  to  $-40^{\circ}\text{C}$  ( $-30$  to  $-40^{\circ}\text{F}$ ).

As indicated in Fig. 7, lower dew points are required as the temperature is lowered. To minimize oxidation during cooling, the chromium-containing alloys must be cooled rapidly in a protective atmosphere.

## 6 WELDING

Cleanliness is the single most important requirement for successful welded joints in nickel alloys. At high temperatures, nickel and its alloys are susceptible to embrittlement by sulfur, phosphorus, lead, and other low-melting-point substances. Such substances are often present in materials used in normal manufacturing/fabrication processes; some examples are grease, oil, paint, cutting fluids, marking crayons and inks, processing chemicals, machine lubricants, and temperature-indicating sticks, pellets, or lacquers. Since it is frequently impractical to avoid the use of these materials during processing and fabrication

Fig. 7 Metal/metal oxide equilibria in hydrogen atmospheres.

of the alloys, it is mandatory that the metal be thoroughly cleaned prior to any welding operation or other high-temperature exposure.

Before maintenance welding is done on high-nickel alloys that have been in service, products of corrosion and other foreign materials must be removed from the vicinity of the weld. Clean, bright base metal should extend 50–75 mm (2–3 in.) from the joint on both sides of the material. This prevents embrittlement by alloying of corrosion products during the welding process. Cleaning can be done mechanically by grinding with a fine grit wheel or disk, or chemically by pickling.

7 MACHINING

Nickel and nickel-base alloys can be machined by the same techniques used for iron-base alloys. However, higher loads will be imparted to the tooling requiring heavy-duty equipment to withstand the load and coolants to dissipate the heat generated. The cutting tool edge must be maintained sharp and have the proper geometry.

8 CLOSURE

There has been a vast amount of nickel-alloy developments since the 1950 edition of *Kent's Mechanical Engineer's Handbook*. It has not been possible to give the composition and discuss each commercial alloy and, therefore, one should refer to publications like Refs. 6–8 for alloy listings, which are revised periodically to include the latest alloys available. (See Table 6 for the producer companies of some of the alloys mentioned in this chapter.)

### 1 INTRODUCTION

Magnesium, with a specific gravity of only 1.74, is the lowest-density metal available for engineering use. It is produced either by electrolytic reduction of  $\text{MgCl}_2$  or by chemical reduction of  $\text{MgO}$  by Si in the form of ferrosilicon.  $\text{MgCl}_2$  is obtained from seawater, brine deposits, or salt lakes.  $\text{MgO}$  is obtained principally from seawater or dolomite. Because of the widespread, easy availability of magnesium ores (e.g., from the ocean), the ore supply is, in human terms, inexhaustible.

### 2 USES

Magnesium is used both as a structural, load-bearing material and in applications that exploit its chemical and metallurgical properties.

#### 2.1 Nonstructural Applications

Because of its high place in the electromotive series, magnesium is used as a sacrificial anode to protect steel from corrosion; some examples are the protection of buried pipelines and the prolongation of the life of household hot-water tanks. Alloys used for this purpose are produced by permanent-mold castings and by extrusion.

Magnesium in powder form is added to gray cast iron to produce ductile, or nodular, iron, an alloy that has many of the producibility advantages of cast iron but is ductile and strong.

A significant use for magnesium powder is its addition to the iron tapped from blast furnaces to remove sulfur prior to converting to steel, thereby increasing the efficiency of the blast furnace and improving the toughness of the steel.

Magnesium powder is also used to produce the Grignard reagent, an organic intermediate used in turn to produce fine chemicals and pharmaceuticals.

Magnesium sheet and extrusions are used to produce photoengravings.

Magnesium in ingot form is one of the principal alloying additions to aluminum, imparting improved strength and corrosion resistance to that metal.

2.2 Structural Applications

Magnesium structures are made from sand, permanent-mold, investment, and die casting, and from sheet, plate, extrusions, and forgings. The base forms produced in these ways are fabricated into finished products by machining, forming, and joining. Finishing for protective or decorative purposes is by chemical-conversion coatings, painting, or electroplating.

The most rapidly growing method of producing structural parts is die casting. This method is frequently the most economical to produce a given part and is especially effective in producing parts with very thin sections. A stimulus for the recent very high growth rate has been the development of a high-purity corrosion-resistant alloy that makes unnecessary the protective finishing of many parts. See alloy AZ91D in Table 1. Die castings are produced by cold chamber,

by hot chamber, and by a recently developed method analogous to the injection molding of plastic parts. The latter technique, known as Thixomolding,<sup>1-4</sup> uses a machine that advances the alloy in a semisolid state by means of a screw and then injects an accumulated amount into the die. The melting step is eliminated, production rates are at least as high as for hot-chamber die casting, and metal quality is superior to that produced by either cold- or hot-chamber die casting. Two major fields dominate the die-casting markets: automotive (e.g., housings, brake pedals, transmissions, instrument panels) and computers (e.g., housings, disc readers).

Those properties mainly significant for structural applications are density (automotive and aerospace vehicle parts; portable tools such as chain saws; containers such as for computers, cameras, briefcases; sports equipment such as catcher's masks, archery bows); high damping capacity (antivibration platforms for electronic equipment; walls for sound attenuation); excellent machinability (jigs and fixtures for manufacturing processes); high corrosion-resistance in an alkaline environment (cement tools).

### 3 ALLOYS AND PROPERTIES

Many alloys have been developed to provide a range of properties and characteristics to meet the needs of a wide variety of applications. The most frequently used are given in Table 1. There are two major classes—one containing aluminum as the principal alloying ingredient, the other containing zirconium. Those containing aluminum are strong and ductile, and have excellent resistance to atmospheric corrosion. Since zirconium is a potent grain refiner for magnesium alloys but is incompatible with the presence of aluminum in magnesium, it is added to all alloys not containing aluminum. Within this class, those alloys containing rare earth or yttrium are especially suited to applications at temperatures ranging to as high as 300°C. Those not containing rare-earth or yttrium have zinc as a principal alloying element and are strong, ductile, and tough.

Recently, the high-purity casting alloys, AZ91E for sand and permanent mold castings and AZ91D, AM60B, AM50A, and AS41B for die castings, have been developed. The high-purity die casting alloys are superior in corrosion resistance to the commonly used aluminum die casting alloy. These alloys have been largely responsible for the large expansion in magnesium automotive applications.

#### 3.1 Mechanical Properties of Castings

Magnesium castings are produced in sand, permanent, investment, pressure die-casting molds.

Castings produced in sand molds range in size from a few pounds to a few thousand pounds and can be very simple to extremely complex in shape. If production runs are large enough to justify higher tooling costs, then permanent instead of sand molds are used. The use of low pressure to fill a permanent mold is a low-cost method that is also used. Investment casting is a specialized technique that permits the casting of very thin and intricate sections with excellent surface and high mechanical properties. Die casting is a process for the production of castings with good dimensional tolerances, good surface, and acceptable properties at quite low cost.

Mechanical properties of cast alloys are given in Table 2.

3.2 Mechanical Properties of Wrought Products

Wrought products are produced as forgings, extrusions, sheet, and plate. Mechanical properties are given in Table 3.

3.3 Physical Properties

A selection of physical properties of pure magnesium is given in Table 4. Most of these are insensitive to alloy addition, but melting point, density, and electrical resistivity vary enough that these properties are listed for alloys in Table 5.

4 FABRICATION

4.1 Machining

Magnesium is the easiest of all metals to machine: it requires only low power and produces clean, broken chips, resulting in good surfaces even with heavy cuts.

4.2 Joining

All standard methods of joining can be used, including welding, riveting, brazing, and adhesive bonding.

Welding is by inert-gas-shielded processes using either helium or argon, and either MIG or TIG. Alloys containing more than 1.5% aluminum should be stress-relieved after welding in order to prevent stress-corrosion cracking due to

Table 2 Typical Mechanical Properties for Castings

residual stresses associated with the weld joint. Rivets for magnesium are of aluminum rather than magnesium. Galvanic attack is minimized or eliminated by using aluminum rivets made of an alloy high in magnesium, such as 5056. Brazing is used, but not extensively, since it can be done only on alloys with a high melting point, such as AZ31B or K1A. Adhesive bonding is straightforward, and no special problems related to magnesium are encountered.

**4.3 Forming**

Magnesium alloys are formed by all the usual techniques, such as deep drawing, bending, spinning, rubber forming, stretch forming, and dimpling.

In general, it is preferable to form magnesium in the temperature range of 150–300°C. While this requires more elaborate tooling, there is some compen-

**Table 4 Physical Properties of Pure Magnesium**

|                             |                                                                                       |
|-----------------------------|---------------------------------------------------------------------------------------|
| Density                     | 1.718 g/cm <sup>3</sup> (Ref. 5)                                                      |

sation in the ability to produce deeper draws (thus fewer tools) and in the elimination or minimizing of springback. Hydraulic rather than mechanical presses are preferred.

## 5 CORROSION AND FINISHING

Magnesium is highly resistant to alkalis and to chromic and hydrofluoric acids. In these environments, no protection is usually necessary. On the other hand, magnesium is less resistant to other acidic or salt-laden environments. While most magnesium alloys can be exposed without protection to dry atmosphere, it is generally desirable to provide a protective finish.

Magnesium is anodic to any other structural metal and will be preferentially attacked in the presence of an electrolyte. Therefore, galvanic contact must be avoided by separating magnesium from other metals by the use of films and tapes. These precautions do not apply in the case of 5056 aluminum alloy, since the galvanic attack in this case is minimal.

Because magnesium is not resistant to acid attack, standing water (which will become acidic by absorption of CO<sub>2</sub> from the atmosphere) must be avoided by providing drain holes.

### 5.1 Chemical-Conversion Coatings

There are a large number of chemical-conversion processes based on chromates, fluorides, or phosphates. These are simple to apply and provide good protection themselves, in addition to being a good paint base.

### 5.2 Anodic Coatings

There are a number of good anodic coatings that offer excellent corrosion protection and also provide a good paint base.

### 5.3 Painting

If a good chemical-conversion or anodic coating is present, any paint will provide protection. Best protection results from the use of baked, alkaline-resistant paints.

## 5.4 Electroplating

Once a zinc coating is deposited chemically, followed by a copper strike, standard electroplating procedures can be applied to magnesium to give decorative and protective finishes.

### 1 INTRODUCTION

The lightweight concept followed recently by the transportation industry made Mg alloys a highly interesting choice for many structural applications. Apart from the high strength-to-weight ratio, Mg alloys exhibit excellent die castability, superior machinability, good ductility, and damping capacity. However, the use of these alloys is far behind that of Al alloys, mainly due to their poor corrosion resistance. Although in rural and some mild industrial environments Mg alloys perform as good as Al and better than mild steel, in wet and salt-containing environments they frequently suffer severe damage. Further detrimental factors to the corrosion resistance of Mg alloys are galvanic coupling, high content of impurities (e.g., heavy metals or fluxes), surface contamination, inadequate surface protection schemes, and poor design. Even in dry environments Mg alloys oxidize easily at high temperatures of application.

The major alloying elements added to Mg in order to obtain the strong, light alloys needed for structural applications are aluminum, manganese, zinc, silicon, zirconium, rare earths (RE), and silver. Two main categories of alloys can be distinguished according to whether they contain Al or Zr. The first category

contains 2–10% of Al; high Al contents improve corrosion resistance, however, ductility and fracture toughness are greater for lower Al contents. AM alloys contain Al and small amounts of Mn, whereas AZ, AS, and AE alloys further contain Zn, Si, and RE, respectively. Alloys from the second group contain no Al but Zr combined with alloying elements such as RE, Zn, and Ag. These alloys generally exhibit improved mechanical properties due to presence of Zr, which has a powerful grain refinement effect on magnesium. Mg alloys can be processed into casting (die, sand, and mold) or used as wrought products (extrusions, forgings, sheet, and plates); castings exceed wrought alloys and account for 85–90% of the total outcome. Detailed information on alloys and processing can be found in Ref. 1.

The prospects for the growing use of structural Mg alloys are particularly attractive but must be supported by the development of more corrosion- and heat-resistant alloys. Currently, the average amount of magnesium used in the production of automobiles is 3 kg and is expected to rise to about 6 kg in 2005.<sup>2</sup> Another major area in which the use of Mg is expanding is the application in electronic housings such as for computers and cell phones, where 100% recyclability, compactness arising from thin walls, and electromagnetic shielding are additional advantages. Applications for Mg alloys in automobiles are variegated and include components such as instrument and door panels, seat frames, gear-box housings, and wheels. Due to aggressive conditions such as salty road splash, high corrosion resistance is required for exterior components. The use of Mg, for example, in engine and transmission components requires additional resistance to higher temperatures. A wider exploitation of the large potential of structural Mg alloys will ultimately depend on a correct use of these alloys in oxidative and corrosive environments.

## 2 OXIDATION

While aqueous corrosion is recognized to be a major problem of Mg alloys, oxidation at elevated temperature is often ignored as a shortcoming for alloy application and is not very widely studied. Magnesium has a high affinity to oxygen and in its presence it rapidly reacts according to:

MgO has a face-centered-cubic (fcc) crystal structure with  $a = 0.42$  nm. It is a cubic close-packing of O ions with metal ions in all octahedral sites. The free energy change that accompanies the formation of the oxide is  $\Delta G_f = -1138$  kJ/mol  $\text{O}_2$  at 25°C<sup>3</sup>; more negative than for most metals with only few exceptions such as Be, Ca, and some rare earths. Therefore, the resistance of Mg and its alloys to oxidation directly depends on the protective properties of the oxide film that forms first.

### 2.1 Ambient Temperature

Despite the very negative free energy of formation of MgO, magnesium exhibits good oxidation resistance in dry air at normal ambient temperature due to the formation of a protective oxide film. Unfortunately, the presence of water in the

environment (humid air or aqueous environments) degrades the film by the formation of a less stable hydrated oxide.

An important criterion to predict the formation of a protective oxide is the Pilling–Bedworth ratio,<sup>4</sup> defined as the ratio of the molecular volume of the oxide to the atomic volume of the metal from which the oxide is formed. If this ratio is less than one as in the case of magnesium ( $V_{\text{MgO}}/V_{\text{Mg}} = 0.81$ ), the oxide grows under internal stress leading to a discontinuous, porous film possessing low protective properties. To explain the good stability of magnesium at low temperatures, it was suggested that initially an unstable structural modification of MgO grows oriented with the metal substrate, building a very thin compact layer. Above a critical oxide thickness, however, the normal cubic lattice forms and the arising stresses lead to cracking of the film.

Generally, it is recognized that the initial oxidation of Mg proceeds by: (1) oxygen chemisorption, (2) formation of the oxide layer (nucleation and lateral growth), and (3) oxide thickening<sup>5–8</sup>; in some cases a “precursor” chemisorption stage before oxide formation was claimed. Initially oxygen is adsorbed on the clean metal surface and forms a chemisorbed monolayer. A rearrangement of valence electrons of the metal and the gas is then necessary for the formation of chemical bonds. In the second stage additional layers of oxide build up forming oxide islands; place exchange and surface diffusion are the important factors. The island growth was reported to be fast and linearly dependent on the oxygen exposure; the oxide thickening stage following coalescence of the oxide islands is slow and diffusion controlled.<sup>9</sup> The film was reported to grow by a field-assisted cation transport mechanism described by Cabrera–Mott kinetics.<sup>10</sup>

A recent study<sup>11</sup> showed that the oxide film naturally formed on pure Mg as a result of exposure to air is thin (20–50 nm) and dense. It exhibits an amorphous structure, which is probably the reason for the protective behavior. In low-humidity atmospheres, no further increase in film thickness is observed. X-ray photoelectron spectroscopy (XPS) data indicated a mixture of elemental Mg, MgO, and 50–60 wt. % Mg(OH)<sub>2</sub>.

Mg–Al alloys form similar films,<sup>12,13</sup> which are largely enriched in Al, especially for alloys containing more than 4% Al. Figure 1 shows that there is a terminal value of about 35% Al that can be incorporated in the oxide: All alloys containing more than 4% Al produce an oxide containing 35% Al; however, if the alloy contains less than 4% Al, the Al level in the oxide never attains 35% and becomes a function of the alloyed Al. The presence of Al in the oxide film causes no chemical shift of the XPS signal for MgO, indicating that the oxide is a mixture of MgO and Al<sub>2</sub>O<sub>3</sub>.

The initial air-formed film on commercial Mg alloys is also dense and protective.<sup>14</sup> The thin film can be visualized by transmission electron microscopy (TEM) analysis on ultramicrotomed cross sections (see Fig. 2); electron diffraction reveals its amorphous structure. Since there is no need for accommodation between the lattice of matrix and oxide, less internal stresses will develop. In addition, amorphous films are in general regarded to have better protective properties than the crystalline ones.<sup>15</sup>

In extended atmospheric exposures of Mg and Mg alloys, the presence of humidity and acid gases as CO<sub>2</sub> and SO<sub>2</sub> alters the composition of the oxide

**Fig. 1** Al concentration in the oxide on homogenized AM alloys (in order to dissolve the  $\beta$  phase) as a function of oxygen exposure.<sup>13</sup>

film. Hydroxides, carbonates, sulfites, or sulfates will form preferentially, thus reducing the film stability.

**2.2 High Temperature**

Most of the work dealing with oxidation of Mg at high temperatures is rather old.<sup>16–20</sup> The rate of oxidation of Mg alloys increases with the temperature obeying an Arrhenius equation. Magnesium hydroxide is not stable at high temperatures and begins to decompose above 350°C.

**Fig. 2** TEM cross section of an oxide film formed naturally on AZ91 alloys exposed to the atmosphere.<sup>14</sup>

At temperatures below 450°C in dry oxygen or at 380°C in moist oxygen, the oxide film formed on magnesium is protective for considerable lengths of time;<sup>16,18</sup> the weight law governing the oxidation is parabolic. However, the MgO film that forms above 450°C is not protective,<sup>16,17,19</sup> and a linear oxidation law is observed. During this degradation of the film, a porous, white oxide grows over the surface, producing a constant oxidation rate. The micromechanism involved in this reaction is yet to be investigated. The activation energy for oxidation between 475 and 575°C was found to be about 211 kJ/mol;<sup>17</sup> this value may represent the true rate of the chemical reaction since in the linear regime oxygen has free access to the reaction surface. Above 600°C oxidation is extremely fast leading to ignition.

A transition in the mechanism of oxidation is also observed in commercial Mg alloys, as exemplified in Fig. 3 for high-purity AM50.<sup>21</sup> Two different regimes were observed in the oxidation curve of AM50 ingots at 450°C: Initially a protective oxide is formed with a parabolic kinetics ( $k_p = 2 \times 10^{-13}$  g<sup>2</sup>/cm<sup>4</sup> · s) and after about 100 min a porous and less protective oxide forms with a linear kinetics ( $k_l = 1.7 \times 10^{-8}$  g/cm<sup>2</sup> · s). Only thin MgO films as formed at the first stages of oxidation are dense and act as a diffusion barrier for both, oxygen and metal cations. Above a certain thickness tensile stresses caused by the unfavorable Pilling–Bedworth ratio are assumed to be too high, and partial cracking of the film is likely to occur, permitting the access of oxygen to the metal surface. Additionally, if cracks allow the metal to become exposed, Mg might, in view of its appreciable vapor pressure, volatilize and react in the vapor phase with the oxygen. The initial protective period gradually shortens with the temperature since the critical thickness is more rapidly attained at higher temperature.

The effect of alloying with various metals nobler than Mg on oxidation was studied by Leontis and Rhines in the temperature range between 400 and 575°C;<sup>17</sup> their results are represented in Fig. 4. Most alloying elements, e.g., Al

Fig. 3 Oxidation kinetics of AM50 ingots at 450°C in natural air (after Ref. 21).

Fig. 4 Effect of alloying elements on the oxidation of Mg at  $\sim 475^\circ\text{C}$  (after Ref. 22, values from Ref. 17).

and Zn, increase the rate of oxidation; only Ce and La improve the resistance of Mg to oxidation. The authors suggested that the increase in oxidation rate results from a lowering of the melting temperature by the various additions. The reactions were considered to take place at the metal/oxide interface. In contrast to Ce and La, which are enriched in the surface layers, all other alloying elements get slightly depleted in the oxide.

Ca and Be are two of the few elements that are more reactive to oxygen than Mg. They are known to have a remarkable effect on the oxidation resistance of Mg,<sup>23</sup> in particular when added together with Al. The addition of as little as 0.001% Be will increase the ignition temperature of Mg by as much as  $200^\circ\text{C}$ . Thus, small additions of Be during melting help to control Mg loss and minimize the use of fluxes. A protective BeO film forms on the surface, reducing drossing and increasing metal yield and cleanliness. These benefits carry over casting. Be provides the further advantage of precipitating Fe and Mg impurities from the melt.

Recent studies<sup>24</sup> performed on conventional AM and AZ alloys at  $450^\circ\text{C}$  confirmed the beneficial effect of RE elements predicted by Leontis and Rhines<sup>17</sup> and showed that Ca strongly improve oxidation performance; rapid solidification (RS) was observed to further reduce the oxidation rate. The results shown in Fig. 5 for AM50 alloys indicate that the modified alloys are very resistant to oxidation. As little as 1% of Ca is enough to reduce the oxidation rate to extremely low values, even for longer oxidation times. Rare earths (added in the form of mischmetal, Mm) are not as effective as Ca, and slightly higher contents are necessary to achieve similar performance (see Fig. 5a).

The oxide formed on alloys with conventional composition is thick and porous, whereas on Ca-containing alloys it is very thin so that metallic glance essentially remains after testing. The film consists of nanocrystalline MgO as

**Fig. 5** Oxidation kinetics of AM50 ingots at 450°C in natural air: (a) effect of Ca and Mn additions and (b) effect of rapid solidification (after Ref. 21).

showed by X-ray diffraction (XRD) and TEM cross sections (for AM50 the grain size  $<40$  nm). In alloys containing Ca an enrichment of Ca in the MgO film in particular in its outermost part was detected by means of atomic emission spectroscopy (AES). Similar Ca enrichment was found in binary Mg–Ca alloys oxidized at 500°C, being identified as CaO.<sup>25</sup> Therefore, the suppression of the oxidation rate of Mg at high temperatures can be attributed to the formation of CaO, which replaces MgO near the surface and acts as a protective layer; similar explanation was given for the protection of the Mg melt by Ca additions.<sup>26</sup> The role of RE in the film formation is still under investigation. There is some evidence that the effect of Ca becomes detrimental at lower temperatures. For example, a recent study on AM50 alloys (same compositions as in Fig. 5) indicated that the presence of 1% Ca increases the oxidation rate at 300°C, while both unalloyed and RE-containing AM50 alloys undergo almost no oxidation at this temperature.<sup>14</sup> Precipitation of Al–Ca intermetallics might be responsible for this deterioration. Measurements at even lower temperatures, within the limit for application of Mg alloys, were not performed yet. Since at lower temperature kinetics becomes very sluggish, extreme long-term measurements would be necessary.

As shown in Fig. 5b, an additional beneficial effect can be achieved by means of RS; the improvement due to Ca and RE remains in the RS material. Until now the influence of RS on the high-temperature oxidation deserved very little attention. It seems that the advantages of RS, e.g., microstructural homogeneity, contribute toward the formation of more stable films as in the case of aqueous corrosion.

In sulfur-containing atmospheres the oxide film produced in the high-temperature range was observed to be more protective.<sup>17</sup> Therefore, addition of SO<sub>2</sub> into the atmosphere retards the oxidation of Mg at high temperatures as

well as during casting. In gases containing  $\text{H}_2\text{S}$  or  $\text{SO}_2$ , magnesium alloys are among the most oxidation-resistant materials.<sup>22</sup> Addition of  $\text{CO}_2$  also suppresses oxidation of solid Mg.<sup>17</sup>

In summary, the interaction of oxygen with Mg leads to the formation of a thin, protective oxide layer. However, temperature as well as moisture accelerate the transition to less protective films. At elevated temperatures the MgO film rapidly attains a critical thickness and starts to crack, thus allowing further oxidation. Ca and RE improve the protective properties of the MgO film and retard the transition into a porous film. Water, if present in the environment, rapidly undermines the protective film leading to a less stable, hydrated oxide and electrochemical dissolution of the metal. This process of aqueous corrosion is the subject of the next section.

### 3 CORROSION

In spite of the great advantages of Mg alloys, their application as engineering material is still restricted by their high susceptibility to corrosion in aqueous environments, especially in the presence of chlorides or when they contain noble metals as impurities. In this section the poor corrosion behavior of Mg alloys and the presently available methods to improve it are discussed. Over the past 30 years important improvements, which include modifications of the bulk alloy and surface, were achieved and nowadays most limitations can be successfully overcome by the correct use of Mg alloys. For further information other recent reviews are recommended.<sup>27,28</sup>

#### 3.1 Electrochemical Properties

In aqueous environments magnesium dissolves electrochemically according to reaction (2) with the formation of magnesium hydroxide and hydrogen, a mechanism that is highly insensitive to the oxygen concentration.<sup>29</sup> If sites for easy hydrogen discharge are available, corrosion can proceed rapidly.

The hydroxide film has a hexagonal structure with alternating layers of Mg and hydroxide ions, thus facilitating easy basal cleavage. Cracking and curling of the film was observed, but it is not clear whether this is caused by the properties of the film or by the evolution of hydrogen gas. The Pilling–Bedworth ratio is 1.77, indicating that the film is under compression. Thus, a combination of internal stresses and the easy basal cleavage may account at least partly for the cracking and curling of the film.<sup>30</sup>

The standard reduction potential of Mg is  $-2.4$  V; at higher potentials Mg corrodes rapidly. Despite the anodic polarization effect arising from the formation of  $\text{Mg}(\text{OH})_2$ , the open-circuit potential in neutral aqueous solutions still falls below  $-1.5$  V. Only at pH values higher than about 11 can a stable layer of  $\text{Mg}(\text{OH})_2$  form and provide protection against further corrosion (see Fig. 6). This protection is highly dependent on the environmental conditions, and Mg turns out to be opposite in character to Al. Mg is resistant to alkalies and poorly buffered environments where the surface pH may increase due to the initial

**Fig. 6** Pourbaix diagram showing the equilibria for Mg-H<sub>2</sub>O system at 25°C.<sup>31</sup> Lines (a) and (b) identify the hydrogen and oxygen evolution reaction, respectively.

$Mg(OH)_2$  formation but not to acids. In contrast Al is resistant to weak acids but attacked by strong alkalis.

### 3.2 Types of Corrosion

Mg alloys undergo both general and localized corrosion. The very electronegative potential of Mg makes these alloys very prone to galvanic corrosion. The galvanic attack can be internal due to microstructural components with more noble potential (e.g., impurities or second phases) or external if Mg is coupled with other metals. While metals with low hydrogen overvoltage (e.g., Ni, Fe, and Cu) constitute efficient cathodes for Mg and cause severe galvanic corrosion, metals that combine an active corrosion potential with a high hydrogen overvoltage (e.g., Al and Zn) are much less damaging. Internal attack can be minimized by selecting high-purity alloys. To avoid external galvanic corrosion, one of the following measures is recommended:<sup>32</sup> (1) Selection of galvanic compatible dissimilar metals (e.g., Al alloys 5052, 5056, and 6061; or tin, cadmium, or zinc-plated ferrous alloys). (2) Protection of Mg and dissimilar metal by suitable surface treatments; painting of the dissimilar metal or even better of both metals is recommended to avoid area effects. (3) Use of insulating washer or gasket between Mg and dissimilar metals to prevent the completion of an electrical circuit. (4) Inhibition of the galvanic cell by using chromates in the sealing compounds or primers. (5) Proper design to avoid electrolyte entrapment.

Intergranular and crevice corrosion are not likely to occur in Mg alloys because the phases at the grain boundaries are always cathodic to the grain interior and the corrosion reaction is insensitive to oxygen concentration differences.<sup>15</sup>

Usually, corrosion concentrates at regions adjacent to second-phase particles and boundaries. Some grains or particles might be undermined and fall out, resulting in higher mass losses than solely due to electrochemical dissolution; this partly explains the so-called negative difference effect observed during anodic polarization of Mg.<sup>27</sup>

As a naturally passive metal, Mg may suffer pitting corrosion. AZ91 in chloride-containing environments exhibits a variety of localized forms of corrosion, including pitting at the outset (initiation sites are few and associated with intermetallic particles), filiform corrosion at early stages of propagation, and a cellular type of attack in the terminal stage.<sup>33–35</sup> The occurrence of filiform corrosion on uncoated surfaces of AZ91, which is not the case for unalloyed, bare Mg,<sup>36</sup> suggests the presence of a more resistant air-formed oxide on the alloy.

Pure Mg is resistant to stress-corrosion cracking (SCC). However, alloying with Al and Zn promotes SCC, which increases with increasing Al content.<sup>1</sup> Thus, Mg–Al–Zn alloys have the greatest susceptibility to SCC. Alloys containing Zr are essentially free from the phenomenon. SCC in Mg alloys<sup>15,37,38</sup> is usually transgranular occurring along twin boundaries or various crystallographic planes. There is general agreement that hydrogen embrittlement is the dominant mechanism. Since hydrogen cannot penetrate the passive film unless it is already damaged, pitting is likely to be the first step on SCC. Therefore, solutions that are nonactive to Mg (such as diluted alkalis, concentrated HF, and chromic acid) or in which general corrosion predominates do not induce SCC. High-humidity content, dissolved oxygen, and seawater accelerate SCC; heavy metal content does not seem to influence it. SCC was studied mainly in Mg–Al systems and information is still lacking for other Mg alloys, in particular for new emerging alloys, e.g., glassy alloys or those containing RE.

### 3.3 Environment and Surface Film

Owing to the very active electrochemical character of Mg, the corrosion behavior of its alloys reflects the protective qualities of the surface film in various environments. As discussed in Section 2.1, in natural environments with low humidity a stable MgO film [or a mixture of MgO and Mg(OH)<sub>2</sub>] forms on magnesium and protection is essentially perfect. Atmospheric corrosion is a threat only in the presence of humidity that leads to condensed water. The corrosion rate of magnesium during exposure to humid air is less than  $10^{-5}$  mm/yr in the absence of condensation, while it becomes greater than  $1.5 \times 10^{-2}$  mm/yr when water condenses on the surface.<sup>39</sup> Hence, for indoor service Mg alloys serve well without any further protection.

Although stable and dense, the air-formed film is permeable to water and soluble Mg species. Exposure to humid air rapidly causes hydration of the oxide and formation of thicker films (e.g., 100–150 nm after 4 days) with a duplex structure.<sup>11,12</sup> The outer layer of the film (20–40 nm) is amorphous and similar to the film formed in dry air (see Fig. 2), but an additional hydrated layer is formed adjacent to the metal. The hydrated layer reduces the passivity of the metal surface by allowing Mg dissolution. This layer is quite sensitive to electron irradiation and develops a cellular structure in the microscope; continued exposure to the electron beam causes release of water and formation of nanocrystalline fcc MgO. Immersion in water leads to the formation at the outermost

surface of a third layer with plateletlike morphology, which probably grows by precipitation of  $\text{Mg}^{2+}$  or other soluble Mg species that migrate outward from the innermost layer. Figure 7 shows schematically the morphology of the layered film formed in the presence of water.

Films formed in water on Mg alloys are sensitive to temperature, agitation, and contaminants.<sup>32</sup> The corrosion rate in water may increase by one or two orders of magnitude when the temperature rises from room temperature to around 100°C.

Immersion in a small volume of stagnant water allows rapid formation of the protective hydroxide film. Owing to the initial dissolution of hydroxide, the pH of the system rises until the point is reached where further dissolution is inhibited and the metal undergoes passivation. Agitation can prevent the pH to rise so that the solubility limit of  $\text{Mg}(\text{OH})_2$  is never reached and corrosion continues at the initial high rate. For example, AZ31B shows little attack in stagnant distilled water, but in constantly replenished water the corrosion rate is significant (0.18 mm/yr).

The presence of small amounts of dissolved salts, in particular chlorides and heavy metal salts, breaks down locally the protective film formed in aqueous environments. All solutions containing salts of heavy metals such as Fe, Ni, and Cu are extremely aggressive because the heavy metal and/or heavy metal basic salt can precipitate to form active cathodes on the anodic Mg surface.

Anions such as chloride, sulfate, and nitrate destroy the passivity of magnesium and cause severe damage. Saline environments such as marine atmospheres, salty road splash, etc. are always harsh environments for Mg alloys, even when protected. For this reason, the majority of corrosion data refer to salt spray test

**Fig. 7** Schema of the three layered oxide formed on Mg and Mg–Al alloys in water-containing environments. (Reprinted from *Corrosion Science*, **39**, J. H. Nordlien, S. Ono, N. Masuko, and K. Nisancioglu, “A TEM Investigation of Naturally Formed Oxide Films on Pure Magnesium,” pp. 1397–1414. Copyright © 1997, with permission from Elsevier Science.)

and immersion in NaCl solutions operated according to the ASTM Standards B117-90 and G31-72, respectively.<sup>40</sup> These data must be interpreted with caution because salt based accelerate tests usually lead to higher corrosion rates than marine atmosphere exposure and show very poor correlation with rural, urban or industrial atmosphere exposure.<sup>32</sup>

The CO<sub>2</sub> in the atmosphere dissolves in water to form carbonic acid, which reacts with the Mg(OH)<sub>2</sub> film to form carbonates.<sup>41</sup> While these films are quite protective, they are slightly soluble in water and do not provide complete protection over extended periods of time. The same is true for other acid-producing compounds, such as SO<sub>2</sub> in industrial atmospheres. Exposure to wet SO<sub>2</sub> was suggested to accelerate the corrosion of magnesium<sup>42</sup> through the conversion of the more protective hydroxide and carbonate compounds to the highly soluble sulfate and sulfite, which are then eroded. If Al is present in the alloy, the effect of CO<sub>2</sub> is smoother due to the formation of hydrotalcite, MgCO<sub>3</sub> · 5Mg(OH)<sub>2</sub> · 2Al(OH)<sub>3</sub> · 4H<sub>2</sub>O, acting as a sealer for the hydroxide film. In the presence of chlorides, the accelerating effect of CO<sub>2</sub> on the atmospheric corrosion rate is rather weak; it becomes more important only for a low degree of salt contamination.<sup>43</sup>

In the presence of fluoride, the film changes from magnesium hydroxide to a very protective magnesium fluoride and protection is greatly increased, even at high temperatures. Mg is even used for constructing handling equipment for concentrated HF. Chromate also forms highly protective films on Mg, and chromic acid is the basis for many protective surface treatments.

A good rule of thumb is that environments that are basic, neutral, or contain fluorine cause little or no corrosion, while environments that are acid do cause corrosion of Mg and its alloys.

### 3.4 Improving Corrosion Resistance

Apart from the influence of the environment, the corrosion behavior of Mg alloys depends (similar to other metallic materials) on the presence of impurities, composition (e.g., type and amount of alloying elements) and processing methods (e.g., type of casting and heat treatment). However, the relative importance of these factors is greatly amplified for all Mg alloys because of the very negative corrosion potential of the matrix combined with the unstable nature of the surface film.

There are four main approaches that can be used to improve the corrosion behavior of Mg alloys: (1) The first approach is the production of high-purity alloys with very low impurity levels; high-purity alloys appeared in the 1980s and presently their use is standard practice. (2) Further important improvements on corrosion can be achieved by alloying with beneficial elements. This is a rather old method, however, in recent years new compositions are being studied. (3) Selective processing that optimizes the microstructure also enhances corrosion resistance; new processing techniques such as RS were shown to be very promising. (4) A further approach, which is complementary to those influencing the alloy itself, is the application of protective films or coatings.

#### Control of Impurities

In general, the factor with the far strongest influence on the corrosion of Mg alloys is the amount of cathodic impurities, particularly of those with low-

hydrogen overvoltage. Noble impurities such as Fe, Cu, and Ni promote microgalvanic corrosion and show tolerance limits above which corrosion rate rapidly increases<sup>44,45</sup> (see Fig. 8). Controlling the level of contamination below these limits reduces the corrosion rate of Mg alloys containing Al by orders of magnitude, making them very competitive. For example, high-purity AZ91 shows lower salt spray corrosion rate than die cast 380 Al and cold-rolled steel<sup>46,47</sup> (see Fig. 8). The individual tolerance limits depend on the specific alloy composition, and a summary can be found in Ref. 27 for common high-purity alloys. For die-cast high-purity AZ91 the ASTM specification B94<sup>48</sup> recommends: Fe < 50 ppm, Ni < 20 ppm, Cu < 300 ppm. Mg alloys containing Zr can be considered to be of high purity because the highly reactive nature of Zr ensures that impurities present in the melt precipitate as compounds before any Zr can dissolve in the Mg matrix.<sup>49</sup> The tolerant limits are important for recycled alloys as well. During recycling care has to be taken to avoid contamination and secondary Mg alloys aiming structural application have to be brought within the ASTM specifications.

The detrimental effect of noble metals decreases as follows: Ni > Fe > Cu. Ni and Cu are usually not a problem because of their very low content in the primary production. Fe is of most concern, especially due to the risk of Fe pick up from carbon steel pots and casting molds. The solubility limit of Fe in Mg is low, and it precipitates as  $\text{Al}_3\text{Fe}$ , which acts as an effective cathode. The detrimental effect of these precipitates is reduced by small additions of Mn (up to 1%) to the melt (e.g., as  $\text{MnCl}_2$ ).<sup>45,50</sup> Manganese forms several Al–Mn–Fe intermetallic particles, which can be removed after settling, and reduces the effect of the remaining Fe containing particles compared to  $\text{Al}_3\text{Fe}$ .<sup>36,50,51</sup> However, Mn should not be alloyed in excess of that necessary to reduce the Fe content to the appropriate level because Fe-free Al–Mn particles also exhibit

**Fig. 8** Influence of Ni, Fe, and Cu impurities on the corrosion rate of die-cast AZ91 in the standard salt spray test.<sup>47</sup> (Reprinted with permission from SAE paper number 850417 © 1985 Society of Automotive Engineers, Inc.)

some cathodic activity, particularly the Mn-rich ones. In addition to the maximum limit for Fe, specifications for high-purity alloys include requirements on the Fe/Mn ratio (e.g., 0.032 and 0.021 for AZ91D and AM60B, respectively).<sup>48</sup>

Poor corrosion resistance is also associated with the presence of nonmetallic inclusions such as chlorides and oxides.<sup>38</sup> The development in the Mg foundry practice, which includes the use of gas mixtures (e.g., SF<sub>6</sub>–air–CO<sub>2</sub>), to protect the melt against excessive oxidation and the elimination of fluxes reduced substantially this concern. For a number of alloys in both cast and wrought conditions, the critical concentration of chloride for pit initiation was reported to range between  $2 \times 10^{-3}$  and  $2 \times 10^{-2}$  M NaCl.<sup>52</sup>

Only if impurities are controlled, other approaches such as the beneficial presence of alloying elements and the use of favorable heat treatments or RS become important.

### Alloying

Keeping in mind the electrochemical properties of magnesium, it is clear that measures to enhance corrosion resistance by alloying require the use of elements with electrochemical potential close to that of magnesium (in order to avoid microgalvanic processes) and ability to help formation of the passive film. The majority of the elements conventionally alloyed to magnesium do not improve significantly corrosion resistance, e.g., addition of Zn and Si. Mn and Zr contribute significantly by reducing the effects of the impurities. The most important benefit is provided by Al, which is simultaneously the most important alloying element of Mg. RE and alkaline metals such as Ca are very attractive in regard to the electrochemical potential, and efforts are being done to develop alloys or to modify current alloys with small amounts of these elements.

**Aluminum.** Commercial Mg–Al alloys contain typically 2–10% of Al. In chloride environments there is a significant decrease in the corrosion rate, independent of the alloy type, as the Al is increased up to 4%. Further increase in the alloyed Al results in a smoother improvement of the corrosion resistance<sup>51</sup> (see Fig. 9).

Alloying with Al results in the precipitation of Mg<sub>17</sub>Al<sub>12</sub> ( $\beta$  phase), in particular along grain boundaries (see Fig. 10a). In addition, there is some evidence for an Al gradient in the matrix, i.e., a decrease from the vicinity of the  $\beta$  phase toward the bulk.<sup>33,35</sup> Mg<sub>17</sub>Al<sub>12</sub> precipitates and Al-rich coring zones act as a barrier against the extension of local corrosion, enhancing the corrosion resistance of Al containing alloys.

The beneficial effect of the  $\beta$  phase results from two effects:<sup>33</sup> (1) It is electrochemically nobler than the Mg matrix while having small cathodic activity as compared to Al–Mn–Fe intermetallics. (2) It is corrosion resistant over a wide pH range (4–14) by combining the passive properties of Mg in alkaline solutions with those of Al in neutral and slightly acidic media. The polarization curve of Mg<sub>17</sub>Al<sub>12</sub> in 5% NaCl saturated with Mg(OH)<sub>2</sub> shows an anodic current plateau<sup>54</sup> suggesting the formation of a partially protective film. The preferential corrosion of the anodically more active bulk matrix (see Fig. 10b) might be the reason for the “honeycomb”-type morphology observed on corroded Al containing alloys.<sup>50,51</sup>

**Fig. 9** Influence of Al concentration on the corrosion rate of die-cast Mg alloys during immersion in 5% NaCl.<sup>51</sup> (Reprinted with the permission from SAE paper number 930755 © 1993 Society of Automotive Engineers, Inc.)

Aluminum additionally improves corrosion resistance by improving the properties of the surface film. With increasing Al content all layers of the film formed on Mg–Al alloys become continuously enriched in  $\text{Al}_2\text{O}_3$  and dehydrated, and layer thickness decreases.<sup>12,13</sup> Such stabilization of the film is especially advantageous for the inner layer, which is responsible for the passivity of the surface in the presence of water. The beneficial changes are significant up to 4% Al in the alloy and cause the sudden decrease in the corrosion rate observed in Fig. 9. Further alloying results in only minor changes in the oxide properties as well as in corrosion resistance. This transition relates with the alumina component in the film. Alloying up to 4% causes the oxide to enrich gradually in Al

**Fig. 10** AZ91 ingots: (a) typical microstructure and (b) preferential dissolution of the matrix and stability of the  $\beta$  phase after 24 h immersion in 5% NaCl solution.<sup>53</sup>

and the film properties to improve. At around 4% of alloyed Al a threshold of 35% Al in the oxide film is achieved and further alloying does not enhance corrosion resistance significantly because the amount of Al in the oxide remains unchanged. Improvements at this composition range have to be correlated with other factors such as an increase of  $\beta$ -phase. The Al threshold agrees well with the composition of oxides grown on the same type of alloys in ultrahigh vacuum and dry air shown in Fig. 1.<sup>13</sup>

Alloying with Al is an effective way to develop corrosion-resistant Mg alloys having surface films with reduced propensity for hydration and ionic conductivity. However, alloying with at least 4% Al is necessary to obtain an oxide with optimum corrosion properties. Only at this threshold the  $\text{Al}_2\text{O}_3$  component forms a continuous passivating network, which could be a skeletal structure in the amorphous mixture of aluminum and magnesium (hydr-)oxides.<sup>12,55</sup>

It was also found that aluminum can have a detrimental effect on corrosion. Al was claimed to decrease the tolerance limit for Fe in an almost linear way<sup>37,56</sup> and in small amounts (below 8%) to produce an anodically more active Mg solid solution.<sup>33</sup> The negative trend in the  $\alpha$  phase, however, reverses for high Al contents.

**Rare Earth (RE) Elements.** Further improvement in the corrosion resistance of Mg–Al alloys can be achieved by alloying with RE elements. RE elements further reduce the hydration of the oxide film, being a possibility to diminish the Al threshold for passivity.<sup>57</sup> The presence of RE promotes the enrichment of the inner oxide layer uniformly with  $\text{Al}_2\text{O}_3$ , also for Al contents in the alloy below the critical value of 4%. The formation of an oxide that is more uniformly enriched in Al agrees with the relatively small effect of RE on the oxide properties in the absence of Al.<sup>57</sup> An enrichment of trace amounts of RE in the oxide film was suggested by several authors but could not be definitely verified.

Another advantage of RE elements is their electrochemical potential, which being very close to that of Mg does not promote galvanic processes. Although RE show a small equilibrium solubility in the Mg matrix in the presence of Al and precipitate as Al–RE particles, these phases are electrochemically passive. Precipitation of  $\text{Al}_4\text{RE}$  was even suggested to enhance corrosion resistance due to the formation of Al coring along the grain boundaries.<sup>51</sup> RE elements also assist in removing Fe from the melt by settling Al–Mn–Fe–RE phases and reduce their cathodic activity.<sup>55,58</sup> Some RE-based intermetallics exhibit high melting temperatures and enhance creep resistance at high temperatures.

Mg–Al–Zn alloys with RE and Mn additions exhibit attractive combination of corrosion resistance, strength, and ductility. These alloys were successfully developed by Allied-Signal's Metals, both by conventionally casting and RS.<sup>59,60</sup> Another standard Mg alloy containing RE is the WE43 [approx. 4% Y, 3.3% Nd + hydrogen reaction equilibrium (HRE)] developed by Magnesium Elektron Ltd., which is a high-strength and corrosion-resistant alloy with long-term stability at higher temperatures. In chloride solutions AE alloys exhibit lower corrosion rates than AS, AM, and AZ alloys with similar Al content (see Fig. 9). Small additions of RE, typically 1–2%, were reported to reduce the dissolution rate of conventional AM alloys by a factor of six.<sup>24</sup>

**Zinc.** The presence of Zn improves corrosion behavior, although this effect is not very remarkable. Zinc has an appreciable solubility in the Mg matrix and the  $\beta$  phase. It is reported to increase the tolerance limits, although to a lesser extent than Mn,<sup>32,44</sup> and to make the Mg(Al) matrix more noble.<sup>33</sup> In alloys containing Al it was suggested to improve the stability of the oxide in the same manner as RE.<sup>13,57</sup> However, a related improvement in the corrosion rate of AZ alloys is not observed probably because Zn also increases the cathodic reaction rate.<sup>54</sup>

**Silicon.** Silicon is added to AS alloys where it increases the strength due to precipitation of  $\text{Mg}_2\text{Si}$  particles.  $\text{Mg}_2\text{Si}$  exhibits a corrosion potential close to that of Mg being relatively innocuous to corrosion behavior.<sup>51</sup> A small fraction of the alloyed Si is present in the form of Al–Mn–Fe–Si compounds and plays a similar role to that of Mn in reducing their cathodic activity.<sup>58</sup>

**Zirconium.** Mg alloys containing Zr generally exhibit good corrosion performance and are relatively insensible to Fe and Ni. Zr combines with Fe to form insoluble particles that precipitate before casting.<sup>37</sup> Since Zr also forms stable compounds with Al or Mn and is removed from the melt, it cannot be added to alloys containing these elements.

**Calcium.** The effect of Ca on the corrosion resistance of Mg is yet to be understood. Regarding the electrochemical potential, addition of Ca should result in low microgalvanic effects and reduce the anodically active area upon precipitation. This was reported for Mg–Ca–Cu splats where precipitation of  $\text{Mg}_2\text{Ca}$  neutralizes the galvanic effect from the  $\text{Mg}_2\text{Cu}$  phase. In the case of RS AZ91 alloy an addition of about 2% Ca improved the corrosion rate from 0.8 to 0.2 mm/yr.<sup>61</sup> However, a detrimental influence of Ca was reported for both conventional and RS binary Mg alloys.<sup>44,62</sup> Alloying conventional AM alloys with small amounts of Ca slightly increases the corrosion rate in NaCl.<sup>24</sup> Films formed on AM50+1%Ca are extremely fine nanocrystalline [identified as  $\text{Mg}_6\text{Al}_2(\text{OH})_{18} \cdot 4.5\text{H}_2\text{O}$  and  $\text{Mg}(\text{OH})_2$ ] and consist of at least two layers (see Fig. 11): A hydrated inner layer, which under electron irradiation develops a cellular structure and transforms into  $\text{MgO}$ , and a thin, more stable outer layer. Similar morphology is observed in films formed on Mg and Mg–Al alloys in water-containing environments (see Fig. 7). Sometimes an additional crystalline layer is observed at the interface alloy/inner layer.

Ca is very unstable in aqueous solutions and  $\text{Ca}(\text{OH})_2$  forms at pH even higher than  $\text{Mg}(\text{OH})_2$ . The presence of  $\text{Ca}(\text{OH})_2$  is not necessarily expected to stabilize the Mg film due to its greater tendency to dissociate chemically in the presence of water.<sup>31</sup> The question whether a combination of Ca and RE is a more promising approach is now under investigation. Mechanical properties and thermal stability also benefit from the presence of Ca and RE.

## Processing

For a given alloy composition corrosion properties are further influenced by the microstructure, which obviously depends on the production process. It is generally accepted that processes resulting in fine-grained, pore-free, and heat-

**Fig. 11** TEM cross section of the film formed on AM50+1%Ca during immersion in NaCl (after Ref. 24).

treatable microstructures enhance corrosion resistance. In this connection, high cooling rates as achieved by new techniques such as RS are very useful.

**Conventional Methods.** Pressure die casting typically takes place at lower temperatures and solidifies in a fraction of time as compared to gravity casting, thus leading to finer microstructures. Die-cast alloys, e.g., AZ91, are generally more corrosion resistant than their mold-cast counterparts.<sup>47</sup> If the matrix grains are fine, a more continuous  $\beta$  phase forms along their boundaries, and the barrier area per material volume is larger.<sup>58</sup> The casting process also affects the size and distribution of cathodic phases formed when impurities are present. In AZ91 alloys the Ni tolerance was reported to be significantly lower for the gravity-cast application than for die-cast application.<sup>47</sup> The Fe tolerance was essentially unaffected by the cast process, being in both cases determined by the amount of Mn present. Heat treatments seem to have no influence on size and distribution of primary phases in the Al–Mn–Fe series.<sup>33</sup>

The corrosion resistance of Mg alloys can be further improved by heat treatments which promote the precipitation of the  $\beta$  phase.<sup>33,54</sup> In fact, the corrosion resistance of AZ91 in the artificially aged condition (T6) is superior than in the as-cast (F) or homogenized (T4) states. A reduction on the maximum pit depth is also observed in artificially aged specimens. Aging causes precipitation of secondary  $\beta$  phase along the grain boundaries and improves the barrier effect against corrosion. On the other hand, solution heat treatment dissolves the  $\beta$  phase and often leads to slightly increased corrosion rates relative to the as-cast condition.

Thixomolding is the high-speed injection molding of thixotropic, semisolid alloys. In the recent years the thixomolding process is becoming popular for production of Mg parts. In this technique fluxes are eliminated because no external melting is required and oxide formation is precluded by the use of an argon atmosphere. Thixomolded materials exhibit less porosity and nonmetallic inclusions. The corrosion rate of thixotropic-molded Mg alloys containing Al is

reduced by 50% or more as compared to die-cast counterparts.<sup>1</sup> This reduction is attributed to an Al enrichment at the surface, due to shear thinning that results in few if any  $\alpha$  particles at the surface, and a reduction in pinhole porosity. Die castings are more prone to porosity (due to the high velocity turbulence of molten metal entering the die) and oxide and flux inclusions.

Micropores should have a detrimental effect on the corrosion resistance of Mg parts due to the following reasons:<sup>27</sup> (1) Autocatalytic corrosion cells can form when electrochemical reactions inside the pore are obstructed by the corrosion products. (2) Micropores result normally from defects in the alloy, which are more active points for corrosion. (3) By increasing the real exposed surface, they increase the corrosion rate (i.e., amount of corrosion per unit area of apparent surface).

**Rapid Solidification (RS).** Rapid solidification introduces important microstructural changes, e.g., significant refinement of matrix and intermetallics, more homogeneous distribution of impurities, metastable extension of the solid solubility, and formation of amorphous phases, which contribute toward the formation of more protective films and the elimination of microgalvanic effects. RS can be successfully applied to Mg alloys.<sup>63</sup> However, one should keep in mind that the industrial feasibility of RS Mg alloys is restricted due to the limited geometry of these materials necessary to achieve high cooling rates. A common method to achieve high cooling rates during solidification is melt spinning. The melt-spun ribbons can be mechanically grounded to powders, sealed in cans, and extruded to produce bars. Another way to overcome the problem of geometry might be the application of the corrosion-resistant RS material at the surface, e.g., by laser melting/alloying.

As in conventional alloys, Al suppresses the corrosion rate of binary RS Mg alloys, in particular for large additions; however, addition of Zn, Si, and Ca enhances it.<sup>62,64</sup> Zinc shows a somewhat anomalous effect, causing the corrosion rate of RS magnesium to increase to a maximum at 18.6% Zn and then decrease with further additions.

RS intensifies the benefits of Al and RE in the stabilization of the passive film in two ways: It increases their solid solubility limits and provides a more homogeneous substrate where it is easier to form the film. The maximum solid solubility of Al in Mg was extended up to 24.5 or 23.4% by splat cooling or melt spinning, respectively.<sup>65,66</sup> In 0.001 M NaCl an anodic plateau develops at low currents, the pitting potential shifts to more noble values, and the corrosion rate decreases by two orders of magnitude when the Al in solid solution is extended from 9.6 to 23.4%.<sup>66</sup> Homogeneous Mg(Al) solid solutions are advantageous because of the formation of Al-stabilized film over the entire surface. Improvements in the passivation behavior in 0.01 M NaCl were also observed in several RS alloys containing RE, e.g., Mg–Zn–Zr–RE (RE = Nd, Ce, or Y), Mg–Nd, and Mg–Y.<sup>67,68</sup> As mentioned above, it is not clear whether RE elements become enriched in the surface film; in RS alloys both enrichment<sup>68,69</sup> and depletion<sup>70</sup> were reported.

If the films become more stable along with a more homogeneous alloy microstructure, susceptibility to pitting should be reduced. This was observed for AZ61, where RS increases the breakdown potential by about 200 mV in Cl<sup>-</sup>

containing solutions.<sup>62</sup> Since pitting is assumed as a necessary precursor to SCC, RS might help to produce SCC-resistant Mg alloys.

RS was also suggested to increase the tolerance limit for Fe.<sup>71</sup> The ennoblement of the matrix with Al and the reduced rate of proton discharge around the refined Fe inclusions were considered to be the origin of this improvement. RS does not necessarily eliminate microgalvanic reaction between Mg matrix and heavy metal precipitates as shown by the higher corrosion rates of RS Mg–Mn alloys containing Ni in comparison with RS pure Mg.<sup>72</sup> However, if RS leads to a sufficiently fine partially crystallized or fully amorphous structure (where heavy metals and Mn are dispersed or even solved), the microgalvanic reaction is suppressed and the corrosion moves to a more general kind.<sup>73,74</sup>

RS Mg–Al–Zn alloys (around 9–21% Al and 3–7% Zn) exhibit up to one order of magnitude lower corrosion rates and better anodic polarization behavior in NaCl than the conventionally cast counterparts.<sup>75</sup> A several years development program on extruded RS Mg–Al–Zn alloys with, e.g., Mn and RE additions, resulted in the evaluation of alloys, e.g., EA55RS (4.8–5.2% Al + 4.7–5.0% Zn + 5.0–5.5% Nd), with better performance than the corrosion resistant AZ91.<sup>76</sup> Figure 12 shows that corrosion rates of RS alloys in NaCl are approaching to those of Al alloys.

Amorphous materials are well known for their improved corrosion resistance, arising from the chemically homogeneous single-phase nature without compositional fluctuations and crystal defects. Glass-forming ability can be found in many Mg systems, e.g., in Mg–Ni, Mg–Cu, Mg–Ln (Ln = lanthanide metal), Mg–Y and Mg–Ca systems often with ternary additions<sup>63</sup> but allows only thin glassy ribbons. Many of these new partially or fully amorphous alloys are attractive, since they attain high corrosion resistance. For example, amorphous and/or nanocrystalline Mg–Y (20–26 at.% Y) films produced by magnetron cosputter deposition perform better in 0.1 M NaCl than pure Mg and even the

**Fig. 12** Corrosion rate of light alloys obtained by weight loss measurements in 5% NaCl solution. \* Data from electrochemical impedance spectroscopy. (Reprinted, by permission from Ref. 61. Copyright © 1996 by Wiley-VCH.)

WE43 alloy.<sup>69</sup> Recently, new perspectives were open with bulk amorphous alloys in the system Mg–TM–Ln (where TM is Ni or Cu and Ln is a lanthanide metal),<sup>77–79</sup> which could be used as structural materials. These glasses display an exceptionally large glass-forming ability and high thermal stability. The supercooled liquid region before crystallization is very wide ( $>60^{\circ}\text{C}$  for  $\text{Mg}_{65}\text{Cu}_{25}\text{Y}_{10}$  and  $>40^{\circ}\text{C}$  for  $\text{Mg}_{50}\text{Ni}_{30}\text{Y}_{20}$ ) and the temperature of crystallization increases with the solute content.<sup>77,80</sup> The most promising bulk amorphous alloy is  $\text{Mg}_{65}\text{Cu}_{25}\text{Y}_{10}$ , which can be produced with a thickness of 4 mm by metallic mold casting and 7 mm by high-pressure die casting<sup>77,78</sup> and exhibits good corrosion resistance.<sup>81,82</sup> Bulk amorphous Mg–Ni–Nd alloys were obtained with a thickness of 3.5 mm and show higher corrosion resistance than AZ91E and EA55RS alloys in 3.5% NaCl solutions.<sup>83</sup>

### Surface Protection

As already pointed out, the films that form on Mg, although quite protective in the absence of humidity and contaminants, do not serve perfectly in all environments. Coatings are used to supplement or replace the natural film, or as better foundation for subsequently applied paint. Direct application of a paint on Mg alloys is difficult due to the basic character of the naturally formed film, typically with a pH of 10.5. Coating can be done by chemical conversion, metal plating, anodization, or application of an organic coat.<sup>84</sup> Effective protection against corrosion usually requires finishing schemes that combine several of these techniques.

Traditional chemical treatments for Mg are generally based on chromate solutions, which are under increasing environmental regulation. With high-purity alloys, selected phosphate treatments can be as effective as chromates. Chemical treatments increase paintability and retard the natural alkali that forms at any point of damage on a painted Mg surface. Used alone they do not provide enough corrosion protection (among other reasons due to their solubility in water).

Any metal that can be electrodeposited can be applied successfully to Mg, but caution should be taken when using electroplating to protect components exposed to corrosive environments. This process is used to attain bright, tarnish-resistant surfaces and to improve wear resistance. In general, plating of Mg consists of a zinc immersion plating and a copper strike, followed by electroplating in standard plating baths. Copper–nickel–chromium plating systems provide good protection, even though galvanic corrosion problems would be expected when the plate is damaged.

Anodic coatings combine reasonable corrosion resistance with excellent paint base qualities and abrasion resistance. These hard ceramiclike coatings exhibit different degrees of inherent porosity. The pores must be sealed to enhance corrosion resistance. The coatings can be filled with polymers such as polytetrafluoroethylene (PTFE) to obtain special properties, e.g., lubricity. Typical anodic coating processes are HAE and Dow 17.<sup>1</sup> Both processes give rise to coatings with thickness in the range of 5–30  $\mu\text{m}$ , consisting mainly of mixed oxides. Anodic coatings represent a special type of chemical conversion coating because some Mg is used to build up the protecting film. The Dow 17 process utilizes a chromate-based formulation. Permanganate is the key ingredient in the

HAE process, however, a chromate sealant is necessary to obtain acceptable corrosion resistance.

Tagnite<sup>85</sup> and Magoxid-Coat<sup>86</sup> are anodic spark processes carried out at higher voltages (final voltage up to about 400 V AC). These anodic coatings are more protective and not based on chromates. The Tagnite process uses a hydroxide–silicate–fluorid electrolyte and the thickness of the coating can be varied between 2 and 30  $\mu\text{m}$  depending on current density and time. Magoxid-Coat is formed in a slightly alkaline electrolyte and results in a partially amorphous oxidic layer based on Mg, Al, and P. The coating consists of a thin barrier layer, a virtually nonporous intermediate ceramic layer responsible for the good corrosion resistance and a very porous outermost ceramic layer. The coating builds up to an optimal thickness of 15–25  $\mu\text{m}$ . Probably, the amorphous nature of the coating contributes toward its improved corrosion behavior. Codeposition of transition metal oxides and organic materials is used to produce additional characteristics, e.g., colored coatings.

Painting of Mg parts may be used to apply a decorative finish or as a mean of protection against corrosion and tarnish. Organic coating can vary from simple oils or waxes to multipaint coatings. If the environment is severe, primers should be based in alkali-resistant vehicles as, e.g., vinyl, epoxy, polyvinyl butyral, acrylic resins, or baked phenolic resins, and contain inhibitive pigments with a slightly soluble chromate.

Following the recent developments of surface engineering, a variety of new surface modification technologies, including ion implantation, chemical vapor deposition/physical vapor deposition (CVD/PVD), and laser surface alloying/melting, can be used to develop more effective and environmental friendly coatings.<sup>87</sup> Hydride coatings were recently proposed as an alternative to chromate coatings.<sup>88</sup> A magnesium hydride or hydrogen-rich layer with thickness of 1–2  $\mu\text{m}$  is created on the Mg surface by cathodic electric charging in aqueous solution. The hydride coating promotes pseudo-passivation of Mg. It can be used either as a stand-alone protective coating or as an effective paint base. Implantation of  $\text{N}^{2+}$  ions on AZ91D surfaces enhances corrosion resistance; an optimal dose of  $5 \times 10^{16}$  ions/ $\text{cm}^2$  results in a corrosion rate approximately 15% of that for the unimplanted alloy.<sup>89</sup>

#### 4 OUTLOOK

Whereas oxidation resistance of Mg alloys is generally considered to be sufficient, at least in the temperature range of typical application, corrosion can still be a problem. Further trends to improve corrosion properties of Mg alloys include: (1) Control of heavy metal content, (2) alloying with elements that stabilize the surface oxide, e.g., RE, and with Mn that improves corrosion behavior due to iron control effect, (3) use of RS techniques, and (4) coating and painting.

Heavy metal impurity control is the key action in the design of highly corrosion resistant Mg alloys. These impurities enhance corrosion by orders of magnitude and only their accurate control gives the indispensable basis for a successful application of all other corrosion protection measures.

In marked contrast to Al and its alloys, Mg does not form a dense protective oxide. The films naturally formed on Mg, although stable in dry environments, are rapidly undermined in the presence of water and contaminants. The usefulness of Mg alloys can be successfully increased by improving the oxide layer

or by applying an appropriate coating. The first approach involves alloy development with the objective of reducing the permeability to water and improving the adhesion to the surface of the air-formed film. This can be achieved by alloying with, e.g., Al and RE, resulting in more stable oxides with reduced propensity for hydration. At least 4% of Al seems to be necessary to form a protective, self-healing film but this threshold is reduced by small additions of RE. RE elements also contribute to improve the oxidation resistance at high temperatures.

RS is a very efficient technique to improve both general and localized corrosion resistance of Mg alloys. Improvements arise from the (1) higher homogeneity of the microstructure, (2) extended solubility of passivation elements, such as Al, and (3) formation of amorphous phases. In terms of corrosion only the material at the surface needs to perform well. Thus, improvements can be obtained by producing an RS alloy surface, e.g., by laser melting/alloying. In general, amorphous materials are particularly resistant against corrosion. Recent developments in amorphous Mg alloys with high thermal stability opened up new prospects to obtain such alloys in bulk castings, especially in the Mg–Cu–Y system.

Thixomolding is an emerging technique especially attractive to produce net-shape Mg parts. Due to the reduced porosity, properties of thixomolded products are generally better than those of die castings.

Despite all these improvements, surface protection will continue to be necessary in harsh environments. New anodic coatings (e.g., Magoxid-Coat) exhibit excellent corrosion and wear resistance. These coatings are environmentally more friendly than the processes based on chromates, a known carcinogen, in the primary coating or sealing baths (e.g., Dow17 and HAE). New emerging hydride coatings may constitute attractive alternatives to the established ones.

### 1 INTRODUCTION

#### 1.1 Purpose

The purpose of this chapter is to provide a reasonable understanding of superalloys so that selection of them for specific designs will be appropriate. Knowl-

edge of superalloy types and their processing will give a potential user the ability to understand the ways in which superalloys can contribute to a design. More importantly, the knowledge provided here should enable the user to ask the important questions of superalloy providers to determine the necessary mechanical property and corrosion/environmental behavior that will influence alloy selection. There is no cookbook for superalloy selection. Proprietary alloys and/or proprietary/restricted processing lead to superalloy conditions and properties not listed in a handbook or catalog of materials. With few exceptions, critical applications will require work with one or more superalloy producers to develop an understanding of what is available and what a superalloy selector/designer can expect from a chosen superalloy.

## 1.2 What Are Superalloys?

Superalloys for purposes of this chapter are those nickel-, iron-nickel-, and cobalt-base corrosion-resistant alloys generally used at temperatures above around 540°C (1000°F). The iron-nickel-base superalloys are an extension of stainless steel technology and generally are wrought, i.e., formed to shape or mostly to shape by hot rolling, forging, etc. The cobalt-base and nickel-base superalloys, on the other hand, may be either wrought or cast depending on the application or the alloy composition involved. The stainless steels, nickel–chromium alloys and cobalt dental alloys that evolved into the superalloys used chromium to provide elevated temperature corrosion resistance. A  $\text{Cr}_2\text{O}_3$  layer on the surface proved very effective in protection against oxidation. Eventually, cast superalloys for the highest temperatures were protected against oxidation by chromium and aluminum. In our opinion, superalloys must contain chromium, probably at the level of 5% (some would argue 8%) or higher.

## 1.3 How Are They Strengthened?

Metals are crystalline and the atoms take various crystallographic forms. Some of these forms tend to be associated with better property characteristics than other crystal structures. By introducing atoms, phases, or grain boundaries, the movement of imperfections that cause deformation to occur is inhibited. The process of modifying composition and microstructure enables materials to be strengthened.

Superalloys consist of an austenitic face-centered-cubic (fcc) crystal structure matrix phase, gamma, plus a variety of secondary phases. Important secondary phases are  $\gamma'$  fcc ordered  $\text{Ni}_3(\text{Al}, \text{Ti})$  and various MC,  $\text{M}_{23}\text{C}_6$ ,  $\text{M}_6\text{C}$ , and  $\text{M}_7\text{C}_3$  (rare) carbides in nickel- and iron-nickel-base superalloys. Carbides are the principal secondary phases in cobalt-base alloys. Also,  $\gamma''$ , a body-centered-tetragonal (bct) phase of ordered  $\text{Ni}_3\text{Nb}$ , a hexagonal ordered  $\text{Ni}_3\text{Ti}$  ( $\eta$ ) phase, and the  $\delta$ -orthorhombic  $\text{Ni}_3\text{Nb}$  intermetallic phase can be found in nickel- and iron-nickel–base superalloys.

It is quite important for the alloy selector to have a realistic understanding of the strengthening process in superalloys as the properties of superalloys can be modified considerably by processing to manipulate the strengthening level achieved. The superalloys derive their strength from solid-solution hardeners and secondary precipitate phases that form in the  $\gamma$  matrix and produce precipitation (age) hardening. Principal strengthening precipitate phases in nickel-base and

iron-nickel-base superalloys are  $\gamma'$  and  $\gamma''$ . Carbides may provide limited strengthening directly (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against movement). The  $\delta$ - and  $\eta$ -phases are useful (along with  $\gamma'$ ) in control of grain structure of wrought superalloys during processing. By controlling grain structure, strength can be significantly influenced. The extent to which the second phases contribute directly to strengthening depends on the alloy and its processing. It should be noted that improper distributions of carbides and precipitate phases can be detrimental to properties.

In addition to those elements that produce solid-solution hardening and/or promote carbide and  $\gamma'$  formation, other elements (e.g., boron, zirconium, hafnium) are added to enhance mechanical or chemical properties. Superalloy microstructure and property control can be complex. As many as 14 elements may be controlled in some superalloys. Some carbide- and  $\gamma'$ -forming elements may contribute significantly to corrosion properties as well. Tables 1 and 2 give a generalized list of the ranges of alloying elements and their effects in superalloys.

1.4 Manufacture of Superalloy Articles

Appropriate compositions of all superalloys can be forged, rolled to sheet, or otherwise formed into a variety of shapes. The more highly alloyed superalloy compositions normally are processed as small castings. Large castings are made only in the weldable superalloy IN 718. Fabricated superalloy structures can be built up by welding or brazing, but the more highly alloyed the superalloy composition (i.e., higher amount of hardening phase), the more difficult it is to weld a superalloy. Machining of superalloys is similar to but more difficult than that of machining stainless steels. In welding or machining of superalloys, the effects of the energy input (heat energy, deformation energy) on the microstructure and properties of the final superalloy product must be considered.

Iron-nickel- and nickel-base superalloys are readily available in extruded, forged, or rolled form; the higher-strength alloys generally are found only in the cast condition. Hot deformation is the preferred forming process, cold forming

Table 1 Common Ranges of Major Alloying Additions in Superalloys

| Element | Range, (%)        |         |
|---------|-------------------|---------|
|         | Fe-Ni and Ni Base | Co Base |
| Cr      | 5-25              | 19-30   |
| Mo, W   | 0-12              | 0-11    |
| Al      | 0-6               | 0-4.5   |
| Ti      | 0-6               | 0-4     |
| Co      | 0-20              | —       |
| Ni      | —                 | 0-22    |
| Nb      | 0-5               | 0-4     |
| Ta      | 0-12              | 0-9     |
| Re      | 0-6               | 0-2     |

usually being restricted to thin sections (sheet). Cold rolling may be used to increase short-time strength properties for applications at temperatures below the lower temperature level of about 540°C (1000°F) established in this chapter for superalloy use. Properties of superalloys generally are controlled by adjustments in chemistry (composition) and by modification of the processing (including heat treatment).

## 1.5 Superalloy Information

While some chemistries and properties are listed in this chapter, there is no substitute for consultation with superalloy manufacturers about the forms (cast, wrought) that can be provided and the exact chemistries available. A few producers are noted at the end of this chapter. Also, it should be understood that not all superalloys are readily available as off-the-shelf items. While literally hundreds, perhaps thousands of superalloy compositions have been evaluated since the mid-1930s, only a handful are routinely produced. Moreover, some superalloys are not available for use in all forms and sizes. Many of the highest strength alloys will only be useful as powder metal products or as castings.

Design data for superalloys are not intended to be conveyed here, but typical properties are indicated for some materials. Design properties should be obtained

from internal testing if possible or from producers or other validated sources if sufficient test data is not available inhouse. Typical properties are merely a guide for comparison. Exact chemistry, section size, heat treatment, and other processing steps must be known to generate adequate property values for design.

The properties of the extraordinary range of superalloy compositions developed over the years are not normally well documented in the literature. However, since many consumers of superalloys actually use only a few alloys, within the customary user groups, data may be more plentiful for certain compositions. The extent to which such data are available to the general public is unknown. However, even if such data were disseminated widely, the alloy selector needs to be aware that processing treatments such as forging conditions, heat treatment, coatings for corrosion protection, etc. dramatically affect properties of superalloys. All data should be reconciled with the actual manufacturing specifications and processing conditions expected. Alloy selectors should work with competent metallurgical engineers to establish the validity of data intended for design as well as to specify the processing conditions that will be used for component production.

Application of design data must take into consideration the probability of components containing locally inhomogenous regions. For wrought superalloys, the probability of occurrence of these regions (which are highly detrimental to fatigue life) is dependent upon the melting method selected (see Section 5 melting for details). For cast superalloys, the degree of inhomogeneity and the likelihood of defects such as porosity is related to the alloy composition and the investment casting technique used to produce a component.

For sources of property data other than that of the producers (melters, forgers, etc.) or an alloy selector's own institution, one may refer to organizations, such as ASM International, that publish compilations of data that may form a basis for the development of design allowables for superalloys.

Standards organizations, such as the American Society for Testing and Materials (ASTM), publish information about superalloys but that information may not ordinarily contain any design data. The great versatility of superalloys in property modification is also a detriment to the universal compilation of property values. The same nominal alloy may have some composition modifications occur from one manufacturer or customer to another. Sometimes this extends from one country to another. Tweaking of the casting or forging process or the heat treatment, in addition to what seem like minor composition changes, can cause significant variations in properties. All facets of chemistry and processing need to be considered when selecting a superalloy for an application.

Nominal compositions of selected superalloys are provided in Table 3. Physical properties of a few superalloys are given in Tables 4 and 5, short-time (tensile) properties in Tables 6 and 7, and time-dependent (creep-rupture) properties in Tables 8 and 9. Selected reference publications for superalloy technical information or properties are indicated in the bibliography.

## 2 METALS AT HIGH TEMPERATURES

### 2.1 General

While material strengths at low temperatures are usually not a function of time, at high temperatures the time of load application becomes very significant for

Table 3 Nominal Compositions of Wrought Superalloys

| Alloy                  | UNS Number    | Composition (%) |      |         |      |      |     |         |      |         |          |                                |

<sup>a</sup> Cold-rolled and solution-annealed sheet, 1.2–1.6 mm (0.048–0.063 in.) thick.

<sup>b</sup> Annealed.

<sup>c</sup> Precipitation hardened.

<sup>d</sup> Work strengthened and aged.

mechanical properties. Concurrently, the availability of oxygen at high temperatures accelerates the conversion of some of the metal atoms to oxides. Oxidation proceeds much more rapidly at high temperatures than at room or lower temperatures.

## 2.2 Mechanical Behavior

In the case of short-time tensile properties (yield strength, ultimate strength), the mechanical behavior of metals at higher temperatures is similar to that at room temperature, but with metals becoming weaker as the temperature increases. However, when steady loads below the normal yield or ultimate strength determined in short-time tests are applied for prolonged times at higher temperatures, the situation is different. Figure 1 illustrates the way in which most materials respond to steady extended-time loads at high temperatures.

Owing to the higher temperature, a time-dependent extension (creep) is noticed under load. If the alloy is exposed for a long time, the alloy eventually fractures (ruptures). The degradation process is called creep or, in the event of failure, creep-rupture (sometimes stress-rupture), and alloys are selected on their ability to resist creep and creep-rupture failure. Data for superalloys frequently are provided as the stress that can be sustained for a fixed time (e.g., 100-h rupture) versus the temperature. Figure 2 shows such a plot with ranges of expected performance for various superalloy families. One of the contributory aspects of elevated temperature failure is that metals tend to come apart at the grain boundaries when tested for long times above about 0.5 of their absolute melting temperature. Thus, fine-grained alloys, which are usually favored for lower temperature applications, may not be the best materials for creep-rupture limited applications at high temperatures. Elimination or reorientation of grain boundaries is sometimes a key factor in maximizing the higher temperature life of an alloy.

**Fig. 1** Creep-rupture schematic showing time-dependent deformation under constant load at constant high temperatures followed by final rupture. (All loads below the short-time yield strength. Roman numerals denote ranges of the creep-rupture curve.)

**Fig. 2** Creep-rupture curves showing ranges for superalloy families. (From *Superalloys Source Book*, ASM International, Materials Park, OH 44073-0002, 1984, p. 3.)

Cyclically applied loads that cause failure (fatigue) at lower temperatures also cause failures in shorter times (lesser cycles) at high temperatures. For example, Fig. 3 shows schematically how the cyclic resistance is degraded at high temperatures when the locus of failure is plotted as stress versus applied cycles (S-N) of load. From the S-N curves shown, it should be clear that there is not necessarily an endurance limit for metals and alloys at high temperatures. Cyclic loads can be induced not only by mechanical loads in a structure, but also by thermal changes. The combination of thermally induced and mechanically induced loads leads to failure in thermal-mechanical fatigue (TMF). TMF failures occur in a relatively low number of cycles. Thus TMF is a low cycle fatigue (LCF) process while lower load mechanical fatigue leads to failure in a high number of cycles (HCF). LCF failures in structures can be mechanically induced or TMF-type. In airfoils in the hot section of gas turbines, TMF is a major concern. In highly mechanically loaded parts, such as gas turbine disks, LCF is the major concern. HCF normally is not a problem with superalloys unless a design error occurs and subjects a component to a high-frequency vibration that forces rapid accumulation of fatigue cycles.

While life under cyclic load (S-N behavior) is a common criterion for design, resistance to crack propagation is an increasingly desired property. Thus, the crack growth rate versus a fracture toughness parameter is required. The parameter in this instance is the stress intensity factor ( $K$ ) range over an incremental distance which a crack has grown—the difference between the maximum and minimum  $K$  in the region of crack length measured. A plot of the resultant type ( $da/dn$  vs.  $\Delta K$ ) is shown in Fig. 4 for several wrought superalloys.

The nature of superalloys is that they resist the creep-rupture process better than other materials, have very good higher temperature short-time strength

(yield, ultimate), very good fatigue properties (including fatigue crack propagation resistance) and combine these mechanical properties with good to exceptional oxidation resistance. Consequently, superalloys are the obvious choice when structures are to operate at higher temperatures. Generally, the temperature range of superalloy operation is broken up into the intermediate range of about 540°C (1000°F) to 760°C (1400°F) and the high-temperature range that occurs above about 816°C (1500°F).

**Fig. 4** Crack growth rate ( $da/dN$ ) versus toughness change ( $\Delta K$ ) curves for several superalloys at 649°C (1200°F). Note that HIP = hot isostatically pressed and H + F = HIP + forge. Unless otherwise noted, all alloys are forged. (From *Superalloys II*, Wiley, 1987, p. 284. Used by permission.)

### 3 PROPERTIES OF SUPERALLOYS

#### 3.1 Physical/Environmental

Iron, cobalt, and nickel, the bases of superalloys, are transition metals located in a similar area of the periodic table of the elements. The density, melting point, and physical properties of the superalloy base elements are given in Table 10. As can be seen, pure iron has a density of 7.87 g/cm<sup>3</sup> (0.284 lb/in.<sup>3</sup>), while pure nickel and cobalt have densities of about 8.9 g/cm<sup>3</sup> (0.322 lb/in.<sup>3</sup>). The superalloys are created usually by adding significant levels of the alloy elements chromium, aluminum, and titanium, plus appropriate refractory metal elements such as tungsten and molybdenum to the base metal. Densities of superalloys are a function of the amounts of these elements in the final compositions. For example, iron-nickel-base superalloys have densities of around 7.9–8.3 g/cm<sup>3</sup> (0.285–0.300 lb/in.<sup>3</sup>), not too dissimilar to densities of nickel-base superalloys, which may range from about 7.8 to 8.9 g/cm<sup>3</sup> (0.282 to 0.322 lb/in.<sup>3</sup>). Cobalt-base superalloy densities, on the other hand, range from about 8.3 to 9.4 g/cm<sup>3</sup> (0.300 to 0.340 lb/in.<sup>3</sup>). Aluminum, titanium, and chromium reduce superalloy

density whereas the refractory elements such as tungsten, rhenium, and tantalum increase it. Table 5 gives density, melting range, and physical properties of some nickel- and cobalt-base superalloys.

The melting temperatures of the basis superalloy elements are nickel at 1452°C (2647°F), cobalt at 1493°C (2723°F), and iron at 1535°C (2798°F). When metals are alloyed, there is no longer a single melting point for a composition. Instead, alloys melt over a range of temperature. The lowest melting temperature (incipient melting temperature) and melting ranges of superalloys are functions of composition and prior processing. Just as the basis metal is higher melting, so generally are incipient melting temperatures greater for cobalt-base superalloys than for nickel- or iron-nickel-base superalloys. Nickel-base superalloys may show incipient melting at temperatures as low as 1204°C (2200°F). However, advanced nickel-base single-crystal superalloys having limited amounts of melting-point depressants tend to have incipient melting temperatures equal to or in excess of those of cobalt-base superalloys.

The physical properties of electrical conductivity, thermal conductivity, and thermal expansion of superalloys tend to be low (relative to other metal systems). These properties are influenced by the nature of the base metals (transition elements) and the presence of refractory-metal additions.

The corrosion resistance of superalloys depends primarily on the alloying elements added and the environment experienced. Contaminants in the atmosphere can cause unexpectedly high corrosion rates. The superalloys employed at the highest temperatures are coated to increase oxidation/corrosion resistance. More information follows later in this chapter.

### 3.2 Mechanical

The superalloys are relatively ductile; the ductilities of cobalt-base superalloys generally are less than those of iron-nickel- and nickel-base superalloys. Short-time tensile ductilities as determined by elongation at failure generally range from as low as 10 pct to as high as around 70 pct, but  $\gamma'$ -hardened alloys are in the lower end, usually between about 10 and 40 pct. Creep-rupture ductilities generally are lower than tensile ductilities. At the 760°C (1400°F) tensile ductility minimum area, creep-rupture ductilities of castings have gone below 1.5 pct; however, most current high-strength PC equiaxed cast alloys have rupture ductilities in excess of 2.0 pct. Single crystal directionally solidified (SCDS) superalloy ductilities can vary with orientation of the single crystal relative to the testing direction.

Superalloys typically have dynamic moduli of elasticity in the vicinity of 207 GPa ( $30 \times 10^6$  psi), although moduli of specific polycrystalline (PC) equiaxed alloys can vary from 172 to 241 GPa ( $25$  to  $35 \times 10^6$  psi) at room temperature depending on the alloy system. Processing that leads to directional grain or crystal orientation can result in moduli of about 124 to 310 GPa (about 18 to  $45 \times 10^6$  psi) depending on the relation of grain or crystal orientation to testing direction. Dynamic measurement of modulus of elasticity at high temperatures is necessary because static modulus is greatly influenced by high temperatures and shows significant reductions over the dynamic value at a common high temperature. Modulus may drop by around 25–30 pct as temperatures increase from room temperature to 871°C (1600°F).

Short-time tensile yield properties of  $\gamma'$ -hardened alloys range from around 550 MPa (80 ksi) to 1380 MPa (200 ksi) at room temperature. Actual values depend on composition and processing (cast vs. wrought). Wrought alloys tend to have the highest values, with the highest hardener content alloys (e.g., Rene 95, IN 100) having the highest strengths. However, strength is a function of grain size and stored energy and alloys such as U630 or IN 718 can be produced with very high yield strengths. Solid-solution-hardened alloys such as the sheet alloy, Hastelloy X, show lower strengths. Ultimate strengths range from around 690 MPa (100 ksi) to 1520 MPa (230 ksi) at room temperature, with  $\gamma'$ -hardened alloys in the high end of the range.

Superalloys tend to show an increase of yield strength from room temperature up to about 760°C (1400°F) and drop off thereafter. This is in contrast to ordinary alloys that tend to continuously decrease in short-time strength as temperatures increase. Ultimate strengths generally do not show this trend. Concurrently, tensile ductility tends to decrease, with a minimum at around 649°C (1200°F). Many published data for alloys do not show any or much of an increase in tensile yield strength over the range to 760°C (1400°F).

The highest tensile properties are found in the finer grain size wrought or powder metallurgy superalloys used in applications at the upper end of the intermediate temperature regime, perhaps to about 760°C (1400°F). The highest creep-rupture properties invariably are found in the coarser grain cast superalloys used in the high-temperature regime. Rupture strengths are a function of the time at which they are to be recorded. The 1000-h rupture stress capability is obviously lower than the 100-h capability. Creep capability also is a function of the amount of creep permitted in a test. For example, the time to 0.5, 1.0, 2.0, and 5.0 pct might each be valuable for design dependent on a component's intended use. It is much more difficult to find this information than it is to find creep-rupture capability information. Handbooks generally do not carry much creep information. Creep-rupture strengths for 100-h failure at 982°C (1800°F) may range from 45 MPa (6.5 ksi) for an older  $\gamma'$ -hardened wrought alloy such as U500 to 205 MPa (30 ksi) for the PC equiaxed cast superalloy Mar-M 246. Columnar grain and single-crystal alloys can be much stronger.

Cyclic properties are not commonly tabulated for superalloys. Properties of interest would be the  $10^3$ – $10^5$  and  $10^6$ – $10^8$  cycle fatigue strength capabilities. This could mean stress for a fixed-cyclic life-to-a-particular-sized crack or stress for a fixed-cyclic life-to-fracture for LCF regimes or only stress for a fixed-cyclic life-to-fracture for HCF regimes. Also, crack propagation rates versus toughness parameter ( $da/dN$  vs.  $\Delta K$ ) are desired. The life values, when available, lend themselves to tabulation, but the  $da/dN$  values are best represented by graphs. LCF strengths are usually related to an alloy's yield strength while HCF strengths are usually related to an alloy's ultimate strength for wrought alloys used at intermediate temperatures. For cast alloys used in the hottest sections of a gas turbine, there appears to be a relation of TMF strength to the creep strength of an alloy for a given alloy form, as for columnar grain directionally solidified (CGCS) nickel-base superalloys.

Superalloys usually are processed to optimize one property in preference to others. The same composition, if used in cast and wrought state, may have different heat treatments applied to the different product forms. Even when a

superalloy is used in the same product form, process treatments may be used to optimize one property over others. For example, an alloy such as Waspaloy was made in wrought form for gas turbine disks. By adjustment of processing conditions, principally heat treatment, substantial yield strength improvements were achieved at the expense of creep-rupture strength.

## 4 EVOLUTION OF SUPERALLOYS

During the first quarter of the twentieth century, chromium was added at various times to cobalt, nickel, and iron. The resulting products were remarkably resistant to atmospheric (moisture-based) environments and to oxidation at high temperatures. By World War II, some of these alloys, including other alloy elements, had come into use for such applications as resistance wires, dental prostheses, cutlery, and furnace and steam turbine components. With the development of the gas turbine engine during the war, the need became apparent for corrosion-resistant materials to operate in demanding mechanical load conditions at high temperatures. At this point, the fledgling superalloy industry began to expand.

By modifying the stainless steels, higher strengths were achieved without the need for special high-temperature strengthening phases. Phases such as  $\eta$  (a nickel–titanium compound) or  $\gamma'$  (a nickel–aluminum compound) had been introduced into the nickel–chromium families of alloys just prior to the war to produce high strength at high temperatures. The increasing temperatures forced alloy developers to include these phases ( $\eta$  and  $\gamma'$ ) in the iron-base alloys to take the high-temperature strength characteristics beyond those of the modified stainless steels such as 19-9DL. Alloys were invented in Germany and, after modification, made their way to the United States as A-286 or V-57 and are still in use today.

Nevertheless, the need for creep-rupture strength continually increased. Some of this need was met in the early years by adapting a cobalt-base corrosion-resistant alloy (vitallium) for use in aircraft engine superchargers and, later, to airfoils in the hot sections of gas turbines. Similar cobalt-base superalloys are still in use today. However, creep-rupture requirements for aircraft gas turbine applications soon outstripped those of the iron-nickel-base superalloys and the cobalt-base superalloys, and so nickel-base superalloys, modified to provide more of the hardening phase  $\gamma'$ , became increasingly used.

### 4.1 Improvement of Superalloys by Chemistry Control

The production of superalloy components initially consists of some sort of melting process. The melting produces ingots that are either remelted, converted to billet, converted to powder for subsequent consolidation to a component, or investment cast. Remelting is used to produce an ingot that can be processed to billet for forging or to mill forms (e.g., bar stock). Until the start of the second half of the twentieth century, melting of superalloys was conducted in air or under slag environments. The properties of modern superalloys derive principally from the presence of many elements that are reactive with oxygen and so were being lost to some degree in the customary melting and casting processes of the time. When vacuum melting techniques were introduced to commercial production of articles, they were pioneered by superalloys. Vacuum melting enabled the production of superalloys containing higher amounts of the hardeners aluminum and titanium. Furthermore, the concurrent reduction in gases, oxides, and

other impurities caused a significant improvement in the ductility of superalloys. With more hardener content, strengths of superalloys began to increase dramatically. Figure 5 shows the improvement in creep-rupture life achieved with the reduction in oxygen content.

## 5 MELTING AND CASTING PRACTICES

### 5.1 General Aspects

The development of superalloys as they are employed today is largely a story of the development of modern melting technology. Whether the final product is to be a forging or an investment casting, the essence of a superalloy's ability to create the properties desired hinges on the correct choice and adaptation of melting principles.

Superalloy melting practices may be classified as either primary (the initial melt of elemental materials and/or scrap that sets the composition) or secondary (remelt of a primary melt for the purpose of controlling the solidification structure). The melt type or combination of melt types selected depends upon both the alloy composition, mill form and size desired, properties desired, and sensitivity of the final component to localized inhomogeneity in the alloy.

### 5.2 Melting and Refining Superalloys

The two most common primary melt practices are argon–oxygen decarburizing treatment of electric arc processed metal (Arc–AOD) and vacuum induction melting (VIM). The two common secondary melt practices are vacuum arc re-

**Fig. 5** Improvement of rupture life at 871°C (1600°F) and 172 Mpa (25 ksi) by reduced oxygen content produced by vacuum melting. (From *Superalloys Source Book*, ASM International, Materials Park, OH 44073-0002, 1984, p. 11.)

melting (VAR) and electro slag remelting (ESR). A few alloy mill products may be manufactured from cast ingots after only primary melting. For the majority of superalloys the common practice combinations are Arc-AOD + ESR, VIM + ESR, VIM + VAR, and VIM + ESR + VAR. Common material specifications, such as Aerospace Materials Specifications (AMS), will specify acceptable melting practices.

The Arc-AOD practice used for superalloys is little different from that used for stainless steels. An electric arc furnace is the recipient of the initial charge and uses power from an arc struck between graphite electrodes and the charge to heat and melt the charge. Once the charge melts, no further electric power is needed. Heat is input into the charge by injecting (“blowing”) oxygen under the surface of the melt to react with elements such as aluminum, titanium, silicon, and carbon. A desulfurizing addition (usually CaO) is made. The slag formed by the oxidation products and the desulfurizing addition is physically removed from the furnace.

The deslagged charge is transferred to the AOD vessel, which is a refractory-lined steel shell with “tuyeres” in the bottom. The tuyeres are used to inject a mixture of argon and oxygen into the molten bath. By controlling the ratio of argon to oxygen, the selective oxidation or reduction of elements may be accomplished. The principal element reduced is carbon. Elements that need to be retained in the melt (particularly chromium) may also be oxidized into the slag. However, additions of aluminum made to the heat will react with the slag and reduce the chromium back into the molten charge. There is no external source of heat to an AOD vessel. The molten charge is heated by making additions of aluminum and oxidizing them. Cooling is accomplished by adding solid scrap to the bath. When the desired composition and pouring temperature are reached, the heat is poured off into a teeming ladle and transferred to the electrode/ingot pouring system. Precautions are taken (shrouding of the pour stream with argon) to minimize the reaction of the pour stream with atmospheric gasses.

The other prevalent primary melt practice is VIM. The VIM furnace consists of a ceramic-lined crucible built up around water-cooled induction coils. The crucible is mounted in a vacuum chamber. The vacuum chamber may have several vacuum ports (of various sizes) built into it so that, without breaking vacuum:

- Charge material may be introduced into the crucible.
- Molds may be introduced into the chamber.
- Systems for removing slag from the pour stream (tundish) may be introduced.
- Sampling of the molten metal may be made for chemistry control.

The charge is separated into three types of components, virgin, reactive, and revert. Note that virgin material is usually elemental material but may also consist of any other type of material that has not been previously vacuum melted. Reactive elements refer to those elements that are strong oxide formers. These are usually the “hardener” elements (titanium, aluminum) in superalloys. Operation of the VIM consists of charging the virgin portion of the charge (minus

the reactive portion) into the crucible. The furnace is pumped down (if not already under vacuum) and a measurement made of the increase in pressure (as a function of time) when the vacuum ports are blanked off. This “leak-up rate” is a measurement of the base furnace vacuum integrity. Power is applied to the induction coils. The magnetic fields produced induce a current in the charge material, heating the charge. When the charge is molten, it will evolve gas (refining). The rate of gas evolution is measured by taking leak-up rates. When consecutive stable leak-up rates are obtained, then refining (degassing) is complete. This produces the lowest possible oxygen in the alloy. Reactive additions are then made and revert is added. (Revert is previously vacuum-melted alloy that is of the same or nearly the same composition as the intended melt.)

Additions of some form of calcium are usually made to reduce sulfur in the charge by forming a CaS slag. A chemistry sample is taken and “trim” additions are made to bring the heat to a precise composition. The metal is (top) poured into the molds through a system for metal transfer which also minimizes slag entrainment and regulation of the pour rate. Cast product for direct processing (e.g., for investment casting) is referred to as ingot. Most often, the VIM product is intended for secondary melting and is referred to as an electrode, as both secondary processes consume this product in an electrically heated process.

Compared to VIM, Arc-AOD uses the lowest cost charge material and has higher production rates. That is, Arc-AOD is the lowest cost process. However, Arc-AOD is limited in its ability to precisely control composition in a narrow range (particularly for superalloys with high titanium levels) and also produces much higher oxygen content material. (Note that the choice of secondary melting process may compensate to some degree for the higher oxide inclusion content of the Arc-AOD process.)

Electro slag remelting is the most frequently used secondary melt process for Arc-AOD electrodes. In ESR, alternating current (AC) is applied to an electrode situated inside a water-cooled crucible containing a slag charge. The intended circuit of current is from the electrode, through the molten slag, through the solidifying ingot, through the water-cooled stool, and by symmetrically located buss bars back to the electrode. The slag is generally a  $\text{CaF}_2$  base, modified by major additions of  $\text{CaO}$ ,  $\text{MgO}$ , and  $\text{Al}_2\text{O}_3$ . Minor additions of  $\text{TiO}_2$  and  $\text{ZrO}_2$  may be made to counteract loss of titanium and zirconium during the melting process. (Note that minor compositional changes may occur during ESR.) The current passing through the slag keeps the slag molten. The molten slag melts the immersed face of the electrode. As the molten metal gathers into drops on the melt surface of the electrode, it is reduced in sulfur (through reaction with the  $\text{CaF}_2$ ) and entrained oxides are incorporated into the slag. The fully formed drop falls through the slag and is collected in the water-cooled crucible. The slag, which has formed a solid layer against the cooled crucible wall, is partially remelted by the molten metal, but remains as a layer between the ingot and the crucible. As the electrode is consumed, an ingot is built up in the crucible. At any given time the ingot contains a pool of molten metal at the ingot top and a zone of liquid + solid between the solid portion of the ingot and the molten pool.

It should be noted that, for a given alloy, there is a critical thickness and angle (to the growth direction) of the liquid + solid zone at which the liquid in

that zone may form self-perpetuating channels in the solidification structure. Such channels are known as “freckles” and are of such high solute content that subsequent thermal treatment cannot eliminate the elemental concentration. Thus, the final product may contain channels of hard particles (from the high solute) which are very detrimental to fatigue properties. The more highly alloyed the material being melted, the smaller and shallower must be the liquid + solid zone in order to avoid freckle formation. The shape and thickness of the liquid + solid zone may be modified to be more resistant to freckle formation by reducing the melt rate (the rate of deposition of molten metal into the pool), reducing the ingot diameter or by improving the heat extraction from the sides of the crucible.

Vacuum arc remelting is used in preference to ESR where larger ingot sizes of highly alloyed materials are needed. VAR is a direct current (DC) process conducted in a vacuum. As occurs in ESR, the electrode is melted into a water-cooled crucible. The melting is accomplished by initially striking an arc between the electrode face and the crucible stool. The arc melts the electrode face and the molten metal collects into drops that fall into the crucible to form an ingot against which the arc is maintained. Because there is no additional source of heat (as, e.g., the cap of molten slag in ESR) and no insulating slag skin on the ingot, the profile of the molten zone in VAR is generally shallower (than in ESR) for any given alloy, melt rate, and ingot diameter combination.

There is no compositional change in VAR with the exception of minor elements with high vapor pressures. Thus, residual amounts of detrimental elements such as bismuth and lead may be removed by VAR. Unfortunately, volatile elements such as magnesium (used for control of sulfide shape) are also removed. The removal of magnesium is generally compensated for by providing an elevated level in the primary melt process.

### 5.3 Pros and Cons of Remelted Ingot Processing

In VAR the interface between the ingot and the crucible does not contain the slag skin found in ESR. Instead, the surface of the ingot, being the first material to solidify, is low in solute elements. More importantly, any oxides or nitrides from the electrode are swept into this surface layer as they melt out of the electrode and onto the surface of the molten pool. This layer is called “shelf.” A disruption in the arc stability may cause the arc to undercut a small section of this shelf. If this section drops into the pool, it is unlikely to remelt and thus forms an alloy lean “spot” that contains layers of entrapped oxide and nitride (“dirt”). These inhomogeneous regions are light or “white” etching and are known as “dirty white spots.” Their generation is triggered by conditions that do not generally leave any electronic signature (at current levels of detection capability) in the VAR records. While robust VAR process parameters and good electrode quality may minimize the frequency of dirty white spot occurrence, their formation cannot be completely avoided. Thus, the possible presence of dirty white spots in a component (and the degree of their degradation of properties) must be considered in material/melt-process selection for a component.

In selecting ESR as the secondary melt practice, positive considerations are that ESR does not generally form dirty white spots, that ESR products may also have better hot workability than VAR products and that the process yield may be modestly higher (lower cost). Negative considerations are that ESR products

cannot be made in large ingot sizes (compared to VAR) without the formation of freckles. The state of the art in ESR controls is such that, at sizes where ESR will normally not form freckles, some undetected abnormality in the melt may cause sufficient disruption that freckles will be produced anyway. ESR is not a robust process (with regard to avoiding defect formation) when operated toward the extreme end of its size capability. However, advances in ESR controls have allowed commercially useful ingots of ESR Waspaloy to be produced while maintaining an adequate distance from the melt regimes where freckle formation would become a concern. More highly alloyed materials (such as IN 718) cannot yet be robustly produced by ESR in similar sizes.

In selecting VAR as the secondary melt practice, positive considerations are that (for a given alloy) VAR will produce a larger ingot (than ESR) without the presence of freckles and that at the selected size the process should be much more robust (in freckle resistance) than is ESR. The principal negative consideration is that dirty white spots will exist in the ingot and that they cannot be detected and their removal assured.

Several producers of critical rotating components in the gas turbine industry have adopted the use of a hybrid secondary melt process: VIM to ensure a low oxygen, precise chemistry initial electrode is followed by ESR. The ESR electrode will be clean and sound but may contain freckles. After VIM + ESR, the clean, sound electrode is then remelted by VAR. The improved cleanliness and soundness of the electrode facilitates VAR control. This product (referred to as “triple melt”) has a much reduced frequency of dirty white spot occurrence compared to double melt (VIM + VAR) product. However, even in triple melt, dirty white spots will occur and must be considered in the component design. The trade-off is the additional cost of an extra processing step versus the enhanced resistance to premature component failure from dirty white spots.

## 6 COMPONENT PRODUCTION

### 6.1 Casting Practices to Produce Parts

The principal casting practice is to use investment casting (also known as the lost wax process). A reverse cast model of the desired component is made and wax is solidified in the resultant die. Then a series of these wax models are joined to a central wax pouring stem. The assembly is coated (invested) with appropriate ceramic, processed to remove wax, and fired to strengthen the invested ceramic mold. An alloy is remelted and cast into the mold. Upon solidification, a series of components in the desired form are attached to the central pouring stem. These objects, frequently turbine hot section airfoil components, are removed and then processed to desired dimensions.

Superalloy investment castings now are available in sizes from a few inches in length up to about 48 in. diameter. Turbine airfoils can now be made not only for aircraft gas turbines but also for land-based power turbines with airfoil lengths of several feet.

Conventional investment castings are polycrystalline (PC) equiaxed with more or less randomly oriented grains. Mechanical properties are nominally random but may show some directionality. Increased property strength levels have been achieved by columnar grain directional solidification (CGDS), which removes

grain boundaries that are perpendicular to the applied principal load in turbine airfoils. Removal of these grain boundaries dramatically improved longitudinal (parallel to airfoil axis) creep-rupture properties of nickel-base cast superalloys. Transverse boundaries continue to be a problem but their effects are minimized by the addition of hafnium, which enhances grain boundary ductility. The ultimate solution is to directionally solidify a superalloy as a single crystal, i.e., a superalloy with no grain boundaries. Maximum creep-rupture strength in nickel-base superalloys now is achieved with single-crystal directionally solidified (SCDS) alloys.

An interesting benefit of directional solidification in nickel-base superalloys is the reduction of the elastic modulus in the primary solidification direction (parallel to the longitudinal axis). Reduced moduli mean less thermal stress on hot section airfoils and thus longer life in TMF.

Selection of cast superalloys is best conducted in conjunction with an investment casting foundry that can indicate the likelihood of success in casting a given design in the alloy selected. Not all alloys are equally good for casting. Casting defects occur and vary with the alloy composition and casting practice. Traditionally, porosity is a major concern, especially with large castings for the cases of gas turbines. Porosity may be controlled by mold design and pouring modifications. Non-surface-connected porosity may be closed by hot isostatic pressing (HIP) of cast articles. Surface porosity in large castings may be repaired by welding. Other casting concerns have included intergranular attack (IGA) caused during chemical removal of molding materials, selectively located coarse grains in PC materials, misorientation and spurious grains in DS alloys, etc. Alloys may be modified in chemistry to optimize product yield but with a possible compromise in properties. Product yield will be an important determinant of final component cost.

## **6.2 Forging and Powder Metal Superalloys**

Forging is the most common method of producing wrought components for superalloy applications. Mill products such as bar stock, wire, etc. are produced, but the most demanding applications use forged wrought ingot metallurgy components. Disks are forged to near-net size or to approximate shape using large presses and appropriate billets from previously produced ingots. The forging process requires the application of heat and pressure to move the alloy from its billet or powder metallurgy preform stage to a finished disk. One or more intermediate shape stages usually are involved when conventional forging is practiced. Isothermal (usually superplastic) forging may go directly from billet to final stage in one step.

As alloy strengths increased, it became increasingly difficult to move the alloy around during forging. Higher pressures were required and defects became more probable. Superplastic forging (isothermal forging) became available in the time frame when the strengths of superalloys were bumping up against metallurgical limits. In addition, the discipline of powder metallurgy opened the way to create billets of the highest strength alloys without the positive segregation defects (of alloy elements) that were making casting and forging of billets to final parts so difficult.

In powder metallurgy, used principally for alloys such as Rene 95, IN 100 or other advanced alloys, a preliminary ingot is remelted and then atomized to small droplets that solidify with limited or no segregation of alloy elements. The powders thus produced are subsequently compacted together by HIP or by extrusion and processed to achieve 100-pct density. The aggregates are homogenous and display uniform properties. Sometimes the powder is pressed to form the final size/shape directly, but usually the powder is compacted to an intermediate stage (e.g., extruded billet) and isothermally forged to final form. Powder metallurgy is expensive, but the savings in subsequent machining costs and the ability to control defects make a reasonable cost trade. Possible defects in PM include carbide stringers and ceramic inclusions from the powder production process.

Conventional alloys such as Waspaloy, U 720, and IN 718 are produced by ingot metallurgy and standard forging practices. High-strength alloys such as Rene 95, IN 100, and Rene 88 generally are produced using powder metallurgy techniques.

### 6.3 Joining

Components of superalloys often could be advantageously produced or repaired by joining processes in the fledgling days of the superalloy industry. That is not necessarily true today. Cobalt-base superalloys, which do not depend on precipitated phases for strength generally are amenable to fusion welding. Sheet metal structures have been fabricated and repair welding is routinely practiced on cobalt-base superalloys. Wrought solution-hardened iron-nickel-base superalloys can be welded, but most precipitation-hardened versions are done with difficulty. Precipitation-hardened alloys tend to crack on fusion welding and properties of many precipitation-hardened alloys are degraded by the heat of the joining processes. These same concepts apply to the precipitation-hardened nickel-base superalloys, which become increasingly more difficult to weld as the amount of hardener in an alloy increases. An exception is the nickel-base (sometimes called nickel-iron-base) superalloy IN 718 which uses large amounts of niobium to harden the alloy. Figure 6 shows the relationship between hardener content and weldability for nickel-base superalloys.

While inertia bonding (nonfusion process) has been used to join nickel-base superalloys, conventional fusion welding is not customarily used successfully although electron beam welding may be useful. Other solid-state joining processes such as transient liquid-phase (TLP) bonding have been used with some measure of success.

The essence of the joining situation for superalloys is that nickel-base airfoils are not repair welded if cracks appear. Cobalt-base airfoils, on the contrary, may be welded to extend life. Sheet metal of cobalt-base, solid-solution-strengthened nickel-base and of lower hardener content nickel-base alloys can be joined and repair welded, as can iron-nickel-base alloys. The nickel-base alloy of choice for components requiring welding is IN 718, which, owing to the unique aspects of its hardening by  $\gamma''$ , can be fusion welded with relative ease.

### 6.4 Summary of Manufacturing Process

Figure 7 presents a view of the superalloy manufacturing process. Many producers have been involved in the business of producing superalloys over the

**Fig. 6** Weldability diagram for some  $\gamma'$ -strengthened nickel-base superalloys showing the influence of total age hardening elements (Al plus Ti) on cracking tendency. (From *Superalloys II*, Wiley, 1987, p. 152. Used by permission.)

years. During the past 50 years of progress, many advances have been made. New companies have formed and others gone out of business. Following are some current sources of superalloy expertise in ingot melting, component forging, and article casting:

This list almost certainly will change and only should be used as a guide to locate potential producers. Most consumers deal with the forging and investment casting vendors who produce the product for subsequent final processing. For best control of properties, many consumers maintain liaison with melters and frequently audit all aspects of the manufacturing process. It is vital to remember in superalloy selection that most superalloys are not off-the-shelf consumer items. They are made to user specifications that may vary from user to user and time to time. Diligence in working with the producers will pay dividends in optimum properties and fewer difficulties for users of superalloys. This concept is indigenous to the industry and superalloy users for mission-critical or human-life-critical applications. It is more costly than buying off-the-shelf. For some applications such as in oil development or coal gasification, there may be less stringent controls that permit off-the-shelf purchase of mill products. No forging or investment casting is an off-the-shelf item.

## 7 OTHER ASPECTS OF SUPERALLOY SELECTION

### 7.1 Corrosion and Coatings for Protection

Initial superalloys were intended to achieve strength with adequate oxidation resistance, and this was accomplished with superalloys that contained upward of 20 pct chromium. Oxidation resistance up to temperatures around 982°C (1800°F) was excellent. However, to increase the design flexibility of nickel-base superalloys, chromium content was reduced to permit more hardener to be added. Concurrently, some superalloys were put into service with environments (e.g., marine salts) that intensified oxidation or ion-induced attack such as hot corrosion. Also, the operating temperatures (surface environment temperatures) to which the alloys are exposed in the most demanding high-temperature conditions increased with the strength increases of the available alloys.

At higher temperatures, the chromium oxide formed during prior heat treatment was less protective and did not regenerate with exposure to high temperatures. General oxidation and intergranular oxidation along the grain boundaries of superalloys began to be a problem with chromium-protected superalloys. However, the problem was not as great as anticipated owing to the protective nature of aluminum oxide formed in greater amounts by the higher aluminum values of second- and third-generation  $\gamma'$ -hardened superalloys. Nevertheless, general oxidation occurred and still reduced cross sections, thus effectively increasing stresses in the remaining material. The grain boundary oxidation created notches. The combination of these events was of concern, and to protect against them, coatings were applied to superalloys.

The early coatings were diffusion coatings produced by pack aluminizing or slurry application. Chemistry of the coating was determined by the chemistry of the alloy. Later coatings were produced by overlaying a specific chemistry of a protective nature on the surface of the component using an appropriate physical vapor deposition unit. The diffusion-type coatings can coat internal (non-line-of-sight) surfaces, while the overlay coatings can only coat external surfaces that

can be seen by the coating apparatus. The diffusion coatings are cheaper and, for a given thickness, probably nearly as protective as the overlay coatings. However, the overlay coatings can be made nearly twice as thick as the diffusion coatings, so overlay coatings often are the coatings of choice for turbine airfoil applications. Diffusion coatings are used to coat internal cooling passages in hot-section airfoils. Some commercial diffusion coating processes are available but virtually all overlay coating processes have been developed by superalloy users such as the aircraft gas turbine manufacturers.

Overlay coatings are generally more expensive than diffusion coatings. Some diffusion coatings are deposited in conjunction with precious metals such as gold or platinum. There are significant benefits to this incorporation of the noble metals in the coating but costs do go up.

Coating and corrosion technology are complex and do not lend themselves to a simple overall description and formula for protection. Hot corrosion phenomena are found below about 927°C (1700°F). Coatings and higher chromium content of an alloy act to inhibit surface attack. Coatings, in general, preserve the surface so that a component may be reused by removing and then restoring the coating.

Coating selection will be based on knowledge of oxidation/corrosion behavior in laboratory, pilot-plant, and field tests. Attributes that probably will be required for successful coating selection include:

- High resistance to oxidation and/or hot corrosion
- Ductility sufficient to provide adequate resistance to TMF
- Compatibility with the base alloys
- Low rate of interdiffusion with the base alloy
- Ease of application and low cost relative to improvement in component life
- Ability to be stripped and reapplied without significant reduction of base-metal dimensions or degradation of base-metal properties

## **7.2 Special Alloys for Hot-Corrosion Resistance**

As temperature decreases below about 927°C (1700°F), the amount of hot corrosion attack decreases. At temperatures below around 760°C (1400°F), under certain conditions the hot corrosion mechanism changes. Attack may begin to increase dramatically with decreasing temperature but then decreases once more as temperatures drop below about 649°C (1200°F). In this lower temperature regime, the province of land-based power gas turbines, attack is resisted best by producing chromium oxide on the surface. Consequently, alloys for this region and application are those such as IN 738 specifically designed to have higher chromium levels, sometimes back up above 20 pct. (IN 939 is an alloy in this latter category.) Other alloys were devised for optimum hot corrosion resistance in higher temperature service. Rene 80 and IN 792 are such alloys.

## **7.3 Thermal Barrier Coatings**

Allied with superalloy protective coating technology is the development of ceramic, so-called thermal barrier coatings (TBC). TBCs aim to reduce a superalloy's surface temperature by several hundred degrees, enabling a superalloy to

operate at lower temperatures in a region where the superalloy may have higher strength. TBCs have found use and can be tailored to operate on a wide range of alloys. TBCs make use of overlay coating technology. A thin overlay coat serves as the bond interface between the ceramic of the TBC and the base superalloy.

## **8 ALLOY SELECTION SUMMARY**

### **8.1 Intermediate-Temperature Applications**

#### **Available Alloys**

Wrought alloys generally are used. Waspaloy and Astroloy were standard nickel-base superalloys selected in the past. Waspaloy is available but Astroloy may not be as readily procured. U-720 has found many applications.

Castings may be used for some applications of significant physical size. Large case structures for gas turbines are routinely cast in IN 718. However, in most instances, wrought alloys generally are used. Ductilities and fracture toughness of wrought alloys are better than those of cast alloys. Strength in tensile tests usually is better too. Creep may be of concern but rupture life normally is not an issue. Iron–nickel alloys such as A-286 might be considered as they may have sufficient strength and will be considerably less costly than their nickel-base counterparts. The best alloy to consider is the nickel-base (sometimes called nickel-iron-base) superalloy IN 718.

Superalloy IN 718 is the most widely used superalloy today. As a wrought alloy, it can be made in various strength levels and is the most weldable high-strength superalloy available. IN 718's weldability is a significant factor in its application as large cast cases.

Costs of IN 718 are lower than some other superalloys because of the widespread use of the alloy. IN 718 also is unique in that it contains none of the strategic element cobalt. IN 718 received a significant application boost in the late 1970s when a cobalt “shortage” caused the price of cobalt to soar to astronomical levels. IN 718 at that time faced continued competition from alloys such as Waspaloy and Astroloy. The lack of cobalt in the alloy swung the pendulum to IN 718 and in the succeeding 20 years, IN 718 has solidified its position as the most widely used superalloy.

In lieu of IN 718, alloys such as Waspaloy, U-720, and others can be adapted to designs. Powder metal techniques allow IN 100, Rene 95, and other high-strength and damage-tolerant alloys to be fabricated and used. An important trend in the intermediate temperature area is the development of dual material/property gas turbine disks. One of the major concerns for gas turbine disks is the difficulty of getting all desired properties in one material. Extensive work has been done to validate the position that a disk may be made of more than one material. Demonstrations have shown that creep-resistant rims can be attached to different core materials which emphasize brute-strength and fatigue resistance. Selection of such materials for an application, however, would require extensive alloy/process development.

#### **What to Look for in Wrought Alloys**

If alloys to be used are intended for massive applications such as turbine disks, high tensile yield and ultimate strength are desired. Good tensile ductility is

important and good mechanical LCF behavior with acceptable crack propagation rates at expected load is a must. If an alloy is to be used as sheet, then good formability is a must, coupled with good weldability. Massive parts such as disks can benefit from good forgeability, but such a quality generally does not exist when high tensile strengths are required. Powder metallurgy processing enables production of forged components not otherwise processable. Inspectability of sonic finished shapes is crucial. Cost is a very important factor, but one that may have to be subverted to properties and processing if a desired component is to be made. Of course, use of special processing techniques such as powder metallurgy may enable a part to be formed that could not be made in any other way and so a high cost may be worth paying.

The essence of superalloy selection for intermediate temperature applications is that there are conventional alloys of capability similar to Waspaloy and down that can be procured and forged by conventional means. Similarly, sheet alloys are available that can be manipulated in conventional ways. For the higher strength applications, there are no easy off-the-shelf technologies or alloys that can just be picked from a catalog and put to work. Selection of alloys is a preliminary step that must be expanded upon to get data and components in a reasonable time frame at acceptable costs.

## **8.2 High-Temperature Applications**

### **Available Alloys**

The highest temperature applications invariably require cast superalloys where the requirement of maximum high-temperature strength is concerned. Some applications, such as combustion chambers, may require less strength and sheet alloys are applied. Nickel- and cobalt-base sheet is available. Hastelloy X, IN 617, HA 188, and others have long experience records. HA 230 has been used extensively. Property data generally are available for these alloys. The material purchased is a mill product and normally is readily available.

Turbine airfoil alloys or some combustor nozzles require stronger alloys than the old standby cobalt-base and early nickel-base PC cast alloys. Many of these highest strength alloys are proprietary to various companies, usually aircraft engine providers. The strongest alloys are the single-crystal nickel-base superalloys.

Cast superalloys for the bottom end of the high-temperature application spectrum may be those standbys such as IN 713 or even cobalt-base alloys such as X-40, which have decades of experience. IN 713 is a good general-purpose PC equiaxed casting alloy that also happens to have no cobalt. Alloys for higher temperatures include U-700, Rene 80, IN 792, IN 100 (Rene 100), Mar-M 246, Mar-M 247, Mar-M 200CG (PWA 1422), Rene 125, PWA 1480, Rene N4, and CMSX alloys such as CMSX-6. Some alloys (PWA 1422, Rene 125) are used only as CGDS components and others only as SCDS components (PWA 1480, Rene N4, most CMSX alloys). Alloys such as Rene 80 have been available in CGDS as well as PC equiaxed form. Others such as IN 792 have been available not only as PC equiaxed components but also in single-crystal form. A defining feature of the short list above is that nearly half of the alloys mentioned are associated with specific aircraft gas turbine companies. Although non-U.S. alloys

were omitted from the list, some non-U.S. alloys also tend to be associated with specific manufacturing company ownership. Thus, many of the alloys that satisfy the most demanding environments may not be available for applications outside of their corporate patent realm.

### **What to Look for in Cast Alloys**

If alloys are to be used for turbine airfoils, high creep and creep-rupture strengths are required. To maximize strength, the alloys for the most demanding applications in high-pressure turbine (HPT) sections should be SCDS materials. In addition to maximizing creep-rupture strength, TMF strength is optimized by the reduction in modulus achieved by orienting a specific direction of the superalloy crystal parallel to the airfoil axis. An alloy for the most stringent turbine airfoil applications will have a high melting point and good to excellent oxidation resistance, the ability to accept a coating and good LCF strength at temperatures where the airfoil attachment is made to a disk. These temperatures are around 760°C (1400°F). SCDS processing will also ensure that thin section properties are optimized. As section thickness is reduced, for a fixed load, a superalloy ruptures in less time than a standard thick test bar would fail. The order of property reduction is PC equiaxed, most reduced; CGDS, less; and SCDS, least.

For turbine vanes where no centrifugal load exists, airfoils may be made from PC equiaxed high-strength cast cobalt-base alloys instead of DS processed nickel-base alloys. High incipient melting temperature is desired for first-stage turbine vanes. A special type of superalloy, an oxide dispersion-strengthened (ODS) alloy has been used for turbine vanes in some applications. One such alloy, MA 754, relies on yttria dispersed in a corrosion-resistant nickel-chromium matrix to provide adequate creep-rupture capability. ODS alloys are not common. MA 6000 is another such alloy that may have enough strength for a high-pressure turbine blade in aircraft gas turbines. A problem with PC equiaxed airfoils is that the thermal mechanical stresses are much higher than on CGDS or SCDS parts owing to the higher modulus of PC equiaxed parts. The modulus of the CGDS and SCDS parts may be only 60 pct of the value for the PC equiaxed nickel-base cast alloys. In the most demanding conditions, TMF problems must be minimized by using oriented grain or crystal structures to reduce stresses.

For low-pressure turbine (LPT) airfoils, alloys such as the IN 100 (Rene 100) or IN 792 and Rene 80 PC equiaxed alloys previously used for HPT airfoils may be chosen. If temperatures or stress conditions are sufficiently relaxed, IN 713, U700, or similar first-generation PC equiaxed cast nickel-base superalloys may suffice.

### **9 FINAL COMMENTS**

Many superalloys are available but not so many have been adopted for use. A principal reason for this situation is the high cost of proving the worth and safety of a new material. Within most aircraft engine companies, only a few airfoil alloys and a comparably short list of disk alloys have ever made it to production. Admittedly this list differs from company to company but the message is the same. If an existing alloy works and a new alloy does not offer some benefit

that overrides the development cost of proving up the alloy for its new use, do not change alloys.

If an alloy selector is starting from scratch to pick an alloy for an application, then any commercially available alloy may be fair game. On the other hand, the best alloy may not be available owing to corporate patent protection. Then, selection of another alloy from a superalloy producer may be necessary but may possibly require extensive development costs to get the product in workable form and to determine design properties. If possible, select a known alloy that has more than one supplier and more than one casting or forging source. Work with the suppliers and others in the manufacturing chain to acquire typical or design properties for the alloy in the form it will be used. Generic alloys owned by superalloy melters or developers are best for the alloy selector not associated with one of the big corporate users of superalloys. Companies with proprietary interests usually have nothing to benefit from giving up a technological advantage by sharing design data or even granting a production release to use a proprietary alloy.

Plastics, or polymers, are ubiquitous. Through human ingenuity and necessity natural polymers have been modified to improve their utility and synthetic polymers developed. Synthetic polymers in the form of plastics, fibers, elastomers, adhesives, and coatings have come on the scene as the result of a continual search for man-made substances that can perform better or can be produced at a lower cost than natural materials such as wood, glass, and metal, which require mining, refining, processing, milling, and machining. The use of plastics can

also increase productivity by producing finished parts and consolidating parts. For example, an item made of several metal parts that require separate fabrication and assembly can often be consolidated to one or two plastic parts. Such increases in productivity have led to fantastic growth in macromolecules. Indeed, the use of plastics has increased almost 20-fold in the last 30 years.

Plastics can be classified in various ways. The two major classifications are thermosetting materials and thermoplastic materials. As the name implies, thermosetting plastics or thermosets are set, cured, or hardened into a permanent shape.<sup>1</sup> The curing, which usually occurs rapidly under heat or ultraviolet (UV) light leads to an irreversible cross-linking of the polymer. Thermoplastics differ from thermosetting materials in that they do not set or cure under heat.<sup>2</sup> When heated, thermoplastics merely soften to a mobile, flowable state where they can be shaped into useful objects. Upon cooling, thermoplastics harden and hold their shape. Thermoplastics can be repeatedly softened by heat and shaped.

Thermoplastics can be classified as amorphous or semicrystalline plastics.<sup>2,3</sup> Most polymers are either completely amorphous or have an amorphous component even if they are crystalline. Amorphous polymers are hard, rigid glasses below a sharply defined temperature, which is known as the glass transition temperature. Above the glass transition temperature the amorphous polymer becomes soft and flexible and can be shaped. Mechanical properties show profound changes near the glass transition temperature. Many polymers are not completely amorphous but are semicrystalline. Crystalline polymers have melting points that are above their glass transition temperature. The degree of crystallinity and the morphology of the crystalline phase have an important effect on mechanical properties. Crystalline plastics will become less rigid above their glass transition temperature but will not flow until the temperature is above the crystalline melting point. At ambient temperatures crystalline/semicrystalline plastics have greater rigidity, hardness, density, lubricity, creep resistance, and solvent resistance than amorphous plastics.

Another classification from cost and performance standpoint polymers can be either commodity or engineering plastics.

Another important class of polymeric resins is elastomers. Elastomeric materials are rubberlike polymers with glass transition temperatures below room temperatures. Below that glass transition temperature an elastomer will become rigid and lose its rubbery characteristics.

## 1 COMMODITY THERMOPLASTICS

The commodity thermoplastics include polyolefins and side-chain-substituted vinyl polymers.<sup>4-6</sup>

### 1.1 Polyethylene

Polyethylene (PE) plastics have the largest volume use of any plastics. They are prepared by the catalytic polymerization of ethylene.<sup>7</sup> Depending on the mode of polymerization, there can be three basic types of polyethylene: high-density (HDPE), low-density polyethylene (LDPE) polymer, and linear low-density polyethylene (LLDPE). LDPE is prepared under more vigorous conditions, which result in short-chain branching. LLDPE is prepared by introducing short-branching via copolymerization with a small amount of long-chain olefin.

**Table 1 Typical Property Values for Polyethylenes**

| Property                                 | HDPE        | LLDPE/LDPE  |
|------------------------------------------|-------------|-------------|
| Density (mg/m <sup>3</sup> )             | 0.96–0.97   | 0.90–0.93   |
| Tensile modulus (GPa)                    | 0.76–1.0    | —           |
| Tensile strength (MPa)                   | 25–32       | 4–20        |
| Elongation at break (%)                  | 500–700     | 275–600     |
| Flexural modulus (GPa)                   | 0.8–1.0     | 0.2–0.4     |
| Vicat soft point (°C)                    | 120–129     | 80–98       |
| Brittle temperature (°C)                 | –100 to –70 | –85 to –35  |
| Hardness (Shore)                         | D60–D69     | D45–D55     |
| Dielectric constant (10 <sup>6</sup> Hz) | —           | 2.3         |
| Dielectric strength (MV/m)               | —           | 9–21        |
| Dissipation factor (10 <sup>6</sup> Hz)  | —           | 0.0002      |
| Linear mold shrinkage (in./in.)          | 0.007–0.009 | 0.015–0.035 |

Polyethylene polymers are crystalline thermoplastics that exhibit toughness, near-zero moisture absorption, excellent chemical resistance, excellent electrical insulating properties, low coefficient of friction, and ease of processing. Their heat deflection temperatures are reasonable but not high. The branching in LLDPE and LDPE decreases the crystallinity. HDPE exhibits greater stiffness, rigidity, improved heat resistance, and increased resistance to permeability than LDPE and LLDPE.

Specialty grades of PE include very low density (VLDPE), medium density (MDPE), and ultrahigh-molecular-weight PE (UHMWPE).

Some typical properties of PEs are listed in Table 1.

**Uses.** HDPEs major use is in blow-molded bottles, shipping drums, carboys, automotive gasoline tanks; injection-molded material-handling pallets, crates, totes, trash and garbage containers; household and automotive parts; and extruded pipe products (corrugated, irrigation, sewer/industrial and gas distribution pipes).

LDPE/LLDPEs find major applications in film form for food packaging as a vapor barrier film that include stretch and shrink wrap; for plastic bags such as grocery bags, laundry and dry cleaning bags; for extruded wire and cable insulation; and for bottles, closures and toys.

## 1.2 Polypropylene

Polypropylene (PP) is prepared by the catalyzed polymerization of propylene.<sup>8,9</sup> PP is a highly crystalline thermoplastic that exhibits low density, rigidity, and good chemical resistance to hydrocarbons, alcohols and oxidizing agents, negligible water absorption, excellent chemical properties, and excellent impact/stiffness balance. Its properties appear in Table 2.

**Uses.** End uses for PP are in blow molding bottles and automotive parts; injection-molded closures, appliances, housewares, automotive parts, and toys. PP can be extruded into fibers and filaments for use in carpets, rugs, and cordage.

**Table 2** Typical Property Values for Polypropylenes

|                                              |                      |
|----------------------------------------------|----------------------|
| Density (mg/m <sup>3</sup> )                 | 0.09–0.93            |
| Tensile modulus (GPa)                        | 1.8                  |
| Tensile strength (MPa)                       | 37                   |
| Elongation at break (%)                      | 10–60                |
| Heat deflection temperature at 0.45 MPa (°C) | 100–105              |
| Heat deflection temperature at 1.81 MPa (°C) | 60–65                |
| Vicat soft point (°C)                        | 130–148              |
| Linear thermal expansion (mm/mm·K)           | $3.8 \times 10^{-5}$ |
| Hardness (Shore)                             | D76                  |
| Volume resistivity (Ω·cm)                    | $1.0 \times 10^{17}$ |
| Linear mold shrinkage (in./in.)              | 0.01–0.02            |

**1.3 Polystyrene**

Catalytic polymerization of styrene yields general-purpose polystyrene (GP PS) often called crystal polystyrene. It is a clear, amorphous polymer that exhibits high stiffness, good dimensional stability, moderately high heat deflection temperature, and excellent electrical insulating properties. However, it is brittle under impact and exhibits very poor resistance to surfactants and solvents. Its properties appear in Table 3.

*Uses.* Ease of processing, rigidity, clarity, and low cost combine to support applications in toys, displays, consumer goods, and housewares such as food packaging, audio/video consumer electronics, office equipment, and medical devices. PS foams can readily be prepared and are characterized by excellent low thermal conductivity, high strength-to-weight ratio, low water absorption, and excellent energy absorption. These attributes have made PS foam of special interest as insulation boards for construction, protective packaging materials, insulated drinking cups, and flotation devices.

**1.4 Impact Polystyrene**

Copolymerization of styrene with a rubber, polybutadiene, can reduce brittleness of PS, but only at the expense of rigidity and heat deflection temperature. Depending on the levels of rubber, impact polystyrene (IPS) or high-impact polystyrene (HIPS) can be prepared. These materials are translucent to opaque and

**Table 3** Typical Properties of Styrene Thermoplastics

| Property                                            | PS       | SAN         | IPS/HIPS  | ABS       |
|-----------------------------------------------------|----------|-------------|-----------|-----------|
| Density (mg/m <sup>3</sup> )                        | 1.050    | 1.080       | 1.02–1.04 | 1.05–1.07 |
| Tensile modulus (GPa)                               | 2.76–3.1 | 3.4–3.9     | 2.0–2.4   | 2.5–2.7   |
| Tensile strength (MPa)                              | 41–52    | 65–76       | 26–40     | 36–40     |
| Elongation at break (%)                             | 1.5–2.5  | —           | —         | 15–25     |
| Heat deflection temperature at 1.81 MPa (°C)        | 82–93    | 100–105     | 80–87     | 80–95     |
| Vicat soft point (°C)                               | 98–107   | 110         | 88–101    | 90–100    |
| Notched Izod (kJ/m)                                 | 0.02     | 0.02        | 0.1–0.3   | 0.1–0.5   |
| Linear thermal expansion (10 <sup>−5</sup> mm/mm·K) | 5–7      | 6.4–6.7     | 7.0–7.5   | 7.5–9.5   |
| Hardness (Rockwell)                                 | M60–M75  | M80–M83     | M45, L55  | R69–R115  |
| Linear mold shrinkage (in./in.)                     | 0.007    | 0.003–0.004 | 0.007     | 0.0055    |

generally exhibit poor weathering characteristics. Typical properties appear in Table 3.

### 1.5 SAN (Styrene/Acrylonitrile Copolymer)

Copolymerization of styrene with a moderate amount of acrylonitrile provides a clear, amorphous polymer (SAN) with increased heat deflection temperature and chemical resistance compared to polystyrene. However, impact resistance is still poor. Typical properties appear in Table 3.

*Uses.* SAN is utilized in typical PS-type applications where a slight increase in heat deflection temperature and/or chemical resistance is needed, such as housewares and appliances.

### 1.6 ABS

ABS is a ter-polymer prepared from the combination of acrylonitrile, butadiene, and styrene monomers.<sup>10</sup> Compared to PS, ABS exhibits good impact strength, improved chemical resistance, and similar heat deflection temperature. ABS is also opaque. Properties are a function of the ratio of the three monomers. Typical properties are shown in Table 3.

*Uses.* The previously mentioned properties of ABS are suitable for tough consumer products (refrigerator door liners); interior automotive trim; business machine housings; telephones and other consumer electronics; luggage; and pipe, fittings, and conduit.

### 1.7 Polyvinyl Chloride

The catalytic polymerization of vinyl chloride yields polyvinyl chloride.<sup>11</sup> It is commonly referred to as PVC or vinyl and is second only to polyethylene in volume use. Normally, PVC has a low degree of crystallinity and good transparency. The high chlorine content of the polymer produces advantages in flame resistance, fair heat deflection temperature, good electrical properties, and good chemical resistance. However, the chlorine also makes PVC difficult to process. The chlorine atoms have a tendency to split out under the influence of heat during processing and heat and light during end use in finished products, producing discoloration and embrittlement. Therefore, special stabilizer systems are often used with PVC to retard degradation.

There are two major subclassifications of PVC: rigid and flexible (plasticized). In addition, there are also foamed PVC and PVC copolymers. Typical properties of PVC resins appear in Table 4.

#### Rigid PVC

PVC alone is a fairly good rigid polymer, but it is difficult to process and has low impact strength. Both of these properties are improved by the addition of elastomers or impact-modified graft copolymers—such as ABS and impact acrylic polymers. These improve the melt flow during processing and improve the impact strength without seriously lowering the rigidity or the heat deflection temperature.

*Uses.* With this improved balance of properties, rigid PVCs are used in such applications as door and window frames; pipe, fittings, and conduit; building panels and siding; rainwater gutters and down spouts; credit cards; and flooring.

**Table 4 Typical Property Values for Polyvinyl Chloride Materials**

| Property                                            | General Purpose | Rigid                   | Rigid Foam     | Plasticized        | Copolymer |
|-----------------------------------------------------|-----------------|-------------------------|----------------|--------------------|-----------|
| Density (mg/m <sup>3</sup> )                        | 1.40            | 1.34–1.39               | 0.75           | 1.29–1.34          | 1.37      |

### Plasticized PVC

Flexible PVC is a plasticized material. The PVC is softened by the addition of compatible, nonvolatile, liquid plasticizers. The plasticizers, which are usually used in >20 parts per hundred resins, lower the crystallinity in PVC and act as internal lubricants to give a clear, flexible plastic. Plasticized PVC is also available in liquid formulations known as plastisols or organosols.

**Uses.** Plasticized PVC is used for wire and cable insulation, outdoor apparel, rainwear, flooring, interior wall covering, upholstery, automotive seat covers, garden hose, toys, clear tubing, shoes, tablecloths, and shower curtains. Plastisols are used in coating fabric, paper, and metal and rotationally cast into balls, dolls, etc.

### Foamed PVC

Rigid PVC can be foamed to a low-density cellular material that is used for decorative moldings and trim. Foamed plastisols add greatly to the softness and energy absorption already inherent in plasticized PVC, giving richness and warmth to leatherlike upholstery, clothing, shoe fabrics, handbags, luggage, and auto door panels; as well as energy absorption for quiet and comfort in flooring, carpet backing, auto headliners, etc.

### PVC Copolymers

Copolymerization of vinyl chloride with 10–15% vinyl acetate gives a vinyl polymer with improved flexibility and less crystallinity than PVC, making such copolymers easier to process without detracting seriously from the rigidity and heat deflection temperature. These copolymers find primary applications in flooring and solution coatings.

#### 1.8 Poly(vinylidene chloride)

Poly(vinylidene chloride), PVDC, is prepared by the catalytic polymerization of 1,1-dichloroethylene. This crystalline polymer exhibits high strength, abrasion resistance, high melting point, better than ordinary heat resistance (100°C max-

imum service temperature), and outstanding impermeability to oil, grease, water vapor, oxygen, and carbon dioxide. It is used for packaging films, coatings, and monofilaments.

When the polymer is extruded into film, quenched, and oriented, the crystallinity is fine enough to produce high clarity and flexibility. These properties contribute to widespread use in packaging film, especially for food products that require impermeable barrier protection.

Poly(vinylidene chloride) and/or copolymers with vinyl chloride, alkyl acrylate, or acrylonitrile are used in coating paper, paperboard, or other films to provide more economical, impermeable materials.

A small amount of poly(vinylidene chloride) is extruded into monofilament and tape that is used in outdoor furniture upholstery.

*Uses.* PVDC is used in food packaging where barrier properties are needed. Applications for injection-molded grades are fittings and parts in the chemical industry. PVDC pipe is used in the disposal of waste acids.

1.9 Poly(methyl methacrylate)

The catalytic polymerization of methylmethacrylate yields poly(methyl methacrylate), PMMA, a strong, rigid, clear, amorphous polymer. PMMA has excellent resistance to weathering, low water absorption, and good electrical resistivity. PMMA properties appear in Table 5.

*Uses.* PMMA is used for glazing, lighting diffusers, skylights, outdoor signs, and exterior lighting lenses in cars and trucks.

1.10 Poly(ethylene terephthalate)

Poly(ethylene terephthalate), PET, is prepared from the condensation polymerization of dimethyl terephthalate and ethylene glycol. PET is a crystalline polymer that exhibits high modulus, high strength, high melting point, good electrical properties, and moisture and solvent resistance.

*Uses.* Primary applications of PET include blow-molded beverage bottles, fibers for wash-and-wear, wrinkle-resistant fabrics, and films that are used in food packaging, electrical applications (capacitors, etc.), magnetic recording tape, and graphic arts.

Table 5 Typical Properties of Poly(methyl methacrylate)

| Property                                            | PMMA        |
|-----------------------------------------------------|-------------|
| Density (mg/m <sup>3</sup> )                        | 1.18–1.19   |
| Tensile modulus (GPa)                               | 3.10        |
| Tensile strength (MPa)                              | 72          |
| Elongation at break (%)                             | 5           |
| Notched Izod (kJ/m)                                 | 0.4         |
| Heat deflection temperature at 1.81 MPa (°C)        | 96          |
| Continuous service temperature (°C)                 | 88          |
| Hardness (Rockwell)                                 | M90–M100    |
| Linear thermal expansion (10 <sup>-5</sup> mm/mm·K) | 6.3         |
| Linear mold shrinkage (in./in.)                     | 0.002–0.008 |

## 2 ENGINEERING THERMOPLASTICS

Engineering thermoplastics comprise a special high-performance segment of synthetic plastic materials that offer premium properties.<sup>12,13</sup> When properly formulated, they may be shaped into mechanically functional, semiprecision parts or structural components. Mechanically functional implies that the parts may be subjected to mechanical stress, impact, flexure, vibration, sliding friction, temperature extremes, hostile environments, etc., and continue to function.

As substitutes for metal in the construction of mechanical apparatus, engineering plastics offer advantages such as transparency, lightweight, self-lubrication, and economy in fabrication and decorating. Replacement of metals by plastic is favored as the physical properties and operating temperature ranges of plastics improve and the cost of metals and their fabrication increases.

### 2.1 Polyesters (Thermoplastic)

Poly(butylene terephthalate), PBT, is prepared from the condensation polymerization of butanediol with dimethyl terephthalate.<sup>14,15</sup> PBT is a crystalline polymer that has a fast rate of crystallization that facilitates rapid molding cycles. It seems to have a unique and favorable balance of properties between polyamides and polyacetals. PBT has low moisture absorption, extremely good self-lubricity, fatigue resistance, good solvent resistance, and good maintenance of mechanical properties at elevated temperatures. PBT resins are often used with reinforcing materials such as glass fiber to enhance strength, modulus, and heat deflection temperature. Properties appear in Table 6.

**Uses.** Applications of PBT include gears, rollers, bearing, housings for pumps, and appliances, impellers, pulleys, switch parts, automotive components, and electrical/electronic components. A high-density PBT is used in countertops and sinks.

### 2.2 Polyamides (Nylon)

The two major types of polyamides are nylon 6 and nylon 66.<sup>16,17</sup> Nylon 6, or polycaprolactam, is prepared by the polymerization of caprolactam. Poly(hexamethylene adipamide), or nylon 66, is derived from the condensation polymerization of hexamethylene diamine with adipic acid. Polyamides are crystalline

**Table 6 Typical Properties of Poly(butylene terephthalate)**

| Property                                            | PBT   | PBT + 40%<br>Glass Fiber |
|-----------------------------------------------------|-------|--------------------------|
| Density (mg/m <sup>3</sup> )                        | 1.300 | 1.600                    |
| Flexural modulus (GPa)                              | 2.4   | 9.0                      |
| Flexural strength (MPa)                             | 88    | 207                      |
| Elongation at break (%)                             | 300   | 3                        |
| Notched Izod (kJ/m)                                 | 0.06  | 0.12                     |
| Heat deflection temperature at 0.45 MPa (°C)        | 154   | 232                      |
| Heat deflection temperature at 1.81 MPa (°C)        | 54    | 232                      |
| Hardness (Rockwell)                                 | R117  | M86                      |
| Linear thermal expansion (10 <sup>-5</sup> mm/mm·K) | 9.54  | 1.89                     |
| Linear mold shrinkage (in./in.)                     | 0.020 | <0.007                   |

polymers. Their key features include a high degree of solvent resistance, toughness, and fatigue resistance. Nylons do exhibit a tendency to creep under applied load. Glass fibers or mineral fillers are often used to enhance the properties of polyamides. In addition the properties of nylon are greatly effected by moisture. Properties of nylon 6 and 66 with and without glass fiber appear in Table 7.

**Uses.** The largest application of nylons is in fibers. Molded applications include automotive components, related machine parts (gears, cams, pulleys, rollers, boat propellers, etc.), appliance parts, and electrical insulation.

### Modified Polyamides

Moisture has a profound effect on the properties of polyamides. Water acts as a plasticizer in polyamides and lowers the rigidity and strength while increasing the ductility. Moreover, this increase in moisture has a negative effect on dimensional stability. Polyamides have been modified by blending with poly(phenylene ether), PPE, in order to minimize the effect of moisture.<sup>18-20</sup> In PA/PPE alloys the polyamide is the continuous phase and imparts good solvent resistance. The PPE is a dispersed phase and acts as a reinforcement of the crystalline nylon matrix giving improved stiffness versus the unfilled nylon resin. Since PPE does not absorb any significant amount of moisture, the effect of moisture on properties is reduced. In addition, heat deflection temperatures have been enhanced. Properties are shown in Table 8.

**Uses.** PA/PPE alloys are used in automotive body panels (fenders and quarter panels); automotive wheel covers, exterior truck parts, under-the-hood automotive parts (air intake resonators, electrical junction boxes and connectors), fluid handling applications (pumps, etc.).

## 2.3 Polyacetals

Polyacetals are prepared via the polymerization of formaldehyde or the copolymerization of formaldehyde with ethylene oxide.<sup>15</sup> Polyacetals are crystalline polymers that exhibit rigidity, high strength, solvent resistance, fatigue resis-

**Table 7 Typical Properties of Polyamides**

tance, toughness, self-lubricity, and cold-flow resistance. They also exhibit a tendency to thermally depolymerize and, hence, are difficult to flame retard. Properties are enhanced by the addition of glass fiber or mineral fillers. Typical properties appear in Table 9.

**Uses.** Applications of polyacetals include moving parts in appliances and machines (gears, bearings, bushings, etc.), in automobiles (door handles, etc.), plumbing and irrigation (valves, pumps, faucets, shower heads, etc.), industrial or mechanical products (rollers, bearings, gears, conveyer chains, and housings), and consumer products (cams, zippers, pen barrels, disposable lighters, and combs).

**2.4 Polyphenylene Sulfide**

The condensation polymerization of dichlorobenzene and sodium sulfide yields a crystalline polymer, polyphenylene sulfide (PPS).<sup>21</sup> It is characterized by high heat resistance, rigidity, excellent chemical resistance, low friction coefficient, good abrasion resistance, and electrical properties. PPS is somewhat difficult to process due to the very high melting temperature, relatively poor flow characteristics, and some tendency for slight cross-linking during processing. PPS resins normally contain glass fibers for mineral fillers. Properties appear in Table 10.

**Table 9 Typical Properties of Polyacetals**

| Property                                            | Polyacetal | Polyacetal + 40%<br>Glass Fiber |

| Linear mold shrinkage (in./in.)                     | 0.004                    |

**Uses.** The reinforced materials are used in aerospace applications, chemical pump components, electrical/electronic components, appliance parts, and in automotive applications (electrical connectors, under-the-hood applications).

## 2.5 Polycarbonates

Most commercial polycarbonates are derived from the reaction of bisphenol A and phosgene.<sup>22-24</sup> Polycarbonates (PC) are transparent amorphous polymers. PCs are among the stronger, tougher, and more rigid thermoplastics. Polycarbonates also show resistance to creep and excellent electrical insulating characteristics. Polycarbonate properties are shown in Table 11.

**Uses.** Applications of PC include safety glazing, safety shields, non-breakable windows, automotive taillights, electrical relay covers, various appliance parts and housings, power tool housings, automotive exterior parts, and blow-molded bottles.

**Table 11 Typical Properties of Polycarbonates**

| Property                                            | PC    | PC + 40%<br>Glass Fiber |
|-----------------------------------------------------|-------|-------------------------|
| Density (mg/m <sup>3</sup> )                        | 1.200 | 1.520                   |
| Tensile modulus (GPa)                               | 2.4   | 11.6                    |
| Tensile strength (MPa)                              | 65    | 158                     |
| Elongation at break (%)                             | 110   | 4                       |
| Flexural modulus (GPa)                              | 2.3   | 9.7                     |

### Polycarbonate/ABS Alloys

PC/ABS blends are prepared by extruder blending and offer a unique balance of properties.<sup>22</sup> The addition of ABS improves the melt processing of the blend, which facilitate filling large, thin-walled parts. The toughness of PC—especially at low temperatures—is enhanced by the blending with ABS while maintaining the high strength and rigidity. The properties are a function of the ABS-to-polycarbonate ratio. Properties appear in Table 12.

**Uses.** PC/ABS is used in automotive body panels (doors) and housewares (small appliances). PC/ABS has become the resin of choice for business equipment because of the combination of processing ease and toughness.

### 2.6 Polysulfone

Polysulfone is prepared from the condensation polymerization of bisphenol A and dichlorodiphenyl sulfone.<sup>25–28</sup> The transparent, amorphous resin is characterized by excellent thermo-oxidative stability, high heat resistance, hydrolytic stability, outstanding chemical resistance (acids, bases, and alcohols), and creep resistance. Properties appear in Table 13.

**Table 13 Typical Properties of Polysulfone**

| Property                                            | Polysulfone |
|-----------------------------------------------------|-------------|
| Density (mg/m <sup>3</sup> )                        | 1.240       |
| Tensile modulus (GPa)                               | 2.48        |
| Tensile strength (MPa)                              | 70          |
| Elongation at break (%)                             | 75          |
| Flexural modulus (GPa)                              | 2.69        |
| Flexural strength (MPa)                             | 106         |
| Notched Izod (kJ/m)                                 | 0.07        |
| Heat deflection temperature at 1.81 MPa (°C)        | 174         |
| Constant service temperature (°C)                   | 150         |
| Hardness (Rockwell)                                 | M69         |
| Linear thermal expansion (10 <sup>-5</sup> mm/mm·K) | 5.6         |
| Linear mold shrinkage (in./in.)                     | 0.007       |

**Uses.** Typical applications of polysulfones include microwave cookware, medical and laboratory equipment where repeated sterilization by steam is required, coffee makers, and electrical/electronic components, and chemical processing equipment.

**2.7 Modified Polyphenylene Ether**

Blends of poly(2,6-dimethyl phenylene ether), PPE, with styrenics (i.e., HIPS, ABS, etc.) form a family of modified PPE-based resins.<sup>29–31</sup> These amorphous blends cover a wide range of heat deflection temperatures, which is dependent on the PPE-to-HIPS ratio. They are characterized by outstanding dimensional stability at elevated temperatures, outstanding hydrolytic stability, long-term stability under load, and excellent dielectric properties over a wide range of frequencies and temperatures. Their properties appear in Table 14.

**Uses.** Applications include automotive (instrument panels, trim, etc.), TV cabinets, electrical connectors, pumps, plumbing fixtures, business machines, medical, telecommunication equipment, microwavable food packaging, and appliances.

**2.8 Polyimides**

Polyimides are a class of polymers prepared from the condensation reaction of a carboxylic acid anhydride with a diamine.<sup>32</sup> Thermoplastic and thermoset grades of polyimides are available. The thermoset polyimides are among the most heat-resistant polymers; for example, they can withstand temperatures up to 250°C. Thermoplastic polyimides, which can be processed by standard techniques, fall into two main categories—polyetherimides (PEI) and polyamide-imides (PAI).<sup>33–35</sup>

In general, polyimides have high heat resistance, high deflection temperatures, very good electrical properties, very good wear resistance, superior dimensional stability, outstanding flame resistance, and very high strength and rigidity. Polyimide properties appear in Table 15.

**Table 14 Typical Properties of Modified Polyphenylene Ether Resins**

| Property                                            | 190 Grade | 225 Grade | 300 Grade |
|-----------------------------------------------------|-----------|-----------|-----------|
| Density (mg/m <sup>3</sup> )                        | 1.080     | 1.090     | 1.060     |

| Linear thermal expansion<br>(10 <sup>-5</sup> mm/mm·K) | —         | 5.6            | 2.0                | 3.60           | 1.80               |
| Linear mold shrinkage (in./in.)                        | —         | 0.5            | 0.2                | —              | 0.25               |

**Uses.** Polyimide applications include gears, bushings, bearings, seals, insulators, electrical/electronic components (printed wiring boards, connectors, etc.). PEI is used in transportation (under-the-hood temperature sensors, fuel system components, high-strength transmission and jet engine parts), medical (autoclaveable parts), electrical/electronics, packaging, appliances, industrial (heat and corrosion resistance, air and fluid handling components), cooking utensils, microwave oven components, and structural components. PAI is used in automobile transmissions (thrust washers and seal rings), parts for gas turbine engines, business machines, hot glass-handling equipment, plasma-cutting torches. Polyimide foam is used for thermal and sound-dampening insulation and seat cushions in aerospace, marine, and industrial applications.

3 FLUORINATED THERMOPLASTICS

Fluoropolymers, or fluoroplastics, are a family of fluorine-containing thermoplastics that exhibit some unusual properties.<sup>36–37</sup> These properties include inertness to most chemicals, resistance to high temperatures, extremely low coefficient of friction, weather resistance, and excellent dielectric properties. Mechanical properties are normally low but can be enhanced with glass or carbon fiber or molybdenum disulfide fillers. Properties are shown in Table 16.

3.1 Poly(tetrafluoroethylene)

Poly(tetrafluoroethylene), PTFE, is a crystalline, very heat resistant (up to 250°C), chemical-resistant polymer.<sup>37</sup> PTFE has the lowest coefficient of friction of any polymer. Poly(tetrafluoroethylene) does not soften like other thermoplastics and has to be processed by unconventional techniques (PTFE powder is compacted to the desired shape and sintered).

**Uses.** PTFE applications include nonstick coatings on cookware; non-lubricated bearings; chemical-resistant pipe, fitting valves, and pump parts; high-temperature electrical parts; and gaskets, seals, and packings.

**Table 16 Typical Properties of Fluoropolymers**

| Property                                            | PTFE              | CTFE              | FEP            | ETFE           | ECTFE             |

| Linear mold shrinkage (in./in.)                     | 0.033–0.053       | 0.008             | —              | —              | <0.025            |

### 3.2 Poly(chlorotrifluoroethylene)

Poly(chlorotrifluoroethylene), CTFE, is less crystalline and exhibits higher rigidity and strength than PTFE.<sup>37</sup> Poly(chlorotrifluoroethylene) has excellent chemical resistance and heat resistance up to 200°C. Unlike PTFE, CTFE can be molded and extruded by conventional processing techniques.

**Uses.** CTFE applications include electrical insulation, cable jacketing, electrical and electronic coil forms, pipe and pump parts, valve diaphragms, and coatings for corrosive process equipment and other industrial parts.

### 3.3 Fluorinated Ethylene–Propylene

Copolymerization of tetrafluoroethylene with some hexafluoropropylene produces fluorinated ethylene–propylene polymer, FEP, which has less crystallinity, lower melting point, and improved impact strength than PTFE. FEP can be molded by normal thermoplastic techniques.<sup>37</sup>

**Uses.** FEP applications include wire insulation and jacketing, high-frequency connectors, coils, gaskets, and tube sockets.

### 3.4 Polyvinylidene Fluoride

Polyvinylidene fluoride, PVDF, has high tensile strength, better ability to be processed but less thermal and chemical resistance than FEP, CTFE, and PTFE.<sup>37</sup>

**Uses.** Polyvinylidene fluoride applications include seals and gaskets, diaphragms, and piping.

### 3.5 Poly(ethylene chlorotrifluoroethylene)

The copolymer of ethylene and chlorotrifluoroethylene is poly(ethylene chlorotrifluoroethylene), ECTFE, and has high strength, chemical and impact resistance. ECTFE can be processed by conventional techniques.

| Rubber                                        | ASTM<br>Nomenclature | Outstanding Characteristic                                                                                  | Property Deficiency                                                                                       | Temperature<br>Use Range (°C) |
|-----------------------------------------------|----------------------|-------------------------------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------|-------------------------------|
| Butadiene rubber                              | BR                   | Very flexible; resistance to wear                                                                           | Sensitive to oxidation; poor resistance to fuels and oil                                                  | -100 to 90                    |
| Natural rubber                                | NR                   | Similar to BR but less resilient                                                                            | Similar to BR                                                                                             | -50 to 80                     |
| Isoprene rubber                               | IR                   | Similar to BR but less resilient                                                                            | Similar to BR                                                                                             | -50 to 80                     |
| Isobutylene-isoprene rubber<br>(butyl rubber) | IIR                  | High flexibility; low permeability to air                                                                   | Similar to BR                                                                                             | -45 to 150                    |
| Chloroprene                                   | CR                   | Flame resistant; fair fuel and oil resistance;<br>increased resistance toward oxygen,<br>ozone, heat, light | Poor low-temperature flexibility                                                                          | -40 to 115                    |
| Nitrile-butadiene                             | NBR                  | Good resistance to fuels, oils, and<br>solvents; improved abrasion resistance                               | Lower resilience; higher hysteresis;<br>poor electrical properties; poorer<br>low temperature flexibility | -45 to 80                     |
| Styrene-butadiene rubber                      | SBR                  | Relatively low cost                                                                                         | Less resilience; higher hysteresis;<br>limited low temperature<br>flexibility                             | -50 to 80                     |
| Ethylene-propylene copolymer                  | EPDM                 | Resistance to ozone and weathering                                                                          | Poor hydrocarbon and oil<br>resistance                                                                    | -50 to <175                   |
| Polysulfide                                   | T                    | Chemical resistance; resistance to ozone<br>and weathering                                                  | Creep; low resilience                                                                                     | -45 to 120                    |

**Table 18 Properties of Specialty Elastomers**

| Elastomer                           | ASTM<br>Nomenclature | Temperature<br>Use Range (°C) | Outstanding Characteristic                                                               | Typical Applications                                                                      |
|-------------------------------------|----------------------|-------------------------------|------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------|
| Silicones<br>(polydimethylsiloxane) | MQ                   | -100 to 300                   | Wide temperature range; resistance to aging, ozone, sunlight; very high gas permeability | Seals, molded and extruded goods; adhesives, sealants; biomedical; personal care products |
| Fluoroelastomers                    | CFM                  | -40 to 200                    | Resistance to heat, oils, chemical                                                       | Seals such as O-rings, corrosion resistant coatings                                       |
| Acrylic                             | AR                   | -40 to 200                    | Oil, oxygen, ozone, and sunlight resistance                                              | Seals, hose                                                                               |
| Epichlorohydrin                     | ECO                  | -18 to 150                    | Resistance to oil, fuels; some flame resistance; low gas permeability                    | Hose, tubing, coated fabrics, vibration isolators                                         |
| Chlorosulfonated                    | CSM                  | -40 to 150                    | Resistance to oil, ozone weathering, oxidizing chemicals                                 | Automotive hose, wire and cable, linings for reservoirs                                   |
| Chlorinated polyethylene            | CM                   | -40 to 150                    | Resistance to oils, ozone, chemicals                                                     | Impact modifier, automotive applications                                                  |
| Ethylene-acrylic                    |                      | -40 to 175                    | Resistance to ozone, weathering                                                          | Seals, insulation, vibration damping                                                      |
| Propylene oxide                     |                      | -60 to 150                    | Low temperature properties                                                               | Motor mounts                                                                              |

**Uses.** Poly(ethylene chlorotrifluoroethylene) applications included wire and cable coatings, chemical-resistant coatings and linings, molded lab ware, and medical packing.

### 3.6 Poly(vinyl fluoride)

Poly(vinyl fluoride) films exhibit excellent outdoor durability. It is the least chemical-resistant fluoropolymer.<sup>37</sup>

**Uses.** Poly(vinyl fluoride) uses include glazing, lighting, and coatings on presurfaced exterior building panels.

## 4 THERMOSETS

Thermosetting resins are used in molded and laminated plastics.<sup>38</sup> They are first polymerized into a low-molecular-weight linear or slightly branched polymer or oligomer, which is still soluble, fusible, and highly reactive during final processing. Thermoset resins are generally highly filled with mineral fillers and glass fibers. Thermosets are generally catalyzed and/or heated to finish the polymerization reaction, cross-linking them to almost infinite molecular weight. This step is often referred to as cure. Such cured polymers cannot be reprocessed or reshaped.

The high filler loading and the high cross-link density of thermoset resins results in very high densities and very low ductility, but very high rigidity and good chemical resistance.

### 4.1 Phenolic Resins

Phenolic resins combine the high reactivity of phenol and formaldehyde to form prepolymers and oligomers called resoles and novolacs. These materials are combined with fibrous fillers to give a phenolic resin, which when heated provides rapid, complete cross-linking into highly cured structures. The high cross-linked aromatic structure has high hardness, rigidity, strength, heat resistance, chemical resistance, and good electrical properties.

**Uses.** Phenolic applications include automotive uses (distributor caps, rotors, brake linings), appliance parts (pot handles, knobs, bases, electrical/electronic components (connectors, circuit breakers, switches), and as an adhesive in laminated materials (e.g., plywood).

### 4.2 Epoxy Resins

The most common epoxy resins are prepared from the reaction of bisphenol A and epichlorohydrin to yield low-molecular-weight resins that are liquid either at room temperature or on warming. Each polymer chain usually contains two or more epoxide groups. The high reactivity of the epoxide groups with amines, anhydrides, and other curing agents provides facile conversion into highly cross-linked materials. Cured epoxy resins exhibit hardness, strength, heat resistance, electrical resistance, and broad chemical resistance.

**Uses.** Epoxy resins are used in glass reinforced, high-strength composites in aerospace, pipes, tanks, pressure vessels; encapsulation or casting of various electrical and electronic components (printed wiring boards, etc.); adhesives;

protective coatings in appliances, flooring, and industrial equipment; and sealants.

### 4.3 Unsaturated Polyesters

Unsaturated polyesters are prepared by the condensation polymerization of various diols and maleic anhydride to give a very viscous liquid that is dissolved in styrene monomer. The addition of styrene lowers the viscosity to a level suitable for impregnation and lamination of glass fibers. The low-molecular-weight polyester has numerous fumarate ester units that provide easy reactivity with styrene monomer. Properly formulated glass-reinforced unsaturated polyesters are commonly referred to as sheet molding compound (SMC), or reinforced plastics. In combination with reinforcing materials such as glass fiber, cured resins offer outstanding strength, high rigidity, impact resistance, high strength-to-weight ratio, and chemical resistance. SMC typically is formulated with 50% calcium carbonate filler, 25% long glass fiber, and 25% unsaturated polyester. The highly filled nature of SMC results in high density and brittle easily pitted surface.

Bulk molding compound (BMC) is formulated similar to SMC except  $\frac{1}{4}$ -in. chopped glass is used. The shorter glass length gives easier process but lower strength and impact.

**Uses.** The prime use of unsaturated polyesters is in combination with glass fibers in high-strength composites and in SMC and BMC materials. The applications include transportation markets (large body parts for automobiles, trucks, trailers, buses, and aircraft), marine markets (small- to medium-sized boat hulls and associated marine equipment), building panels, housing and bathroom components (bathtub and shower stalls), appliances, and electrical/electronic components.

### 4.4 Alkyd Resins

Alkyd resins are based on branched prepolymers from glycerol, phthalic anhydride, and glyceryl esters of fatty acids. Alkyds have excellent heat resistance, are dimensionally stable at high temperatures, and have excellent dielectric strength ( $>14$  MV/m), high resistance to electrical leakage, and excellent arc resistance.

**Uses.** Alkyd resin applications include drying oils in enamel paints, lacquers for automobiles and appliances; and molding compounds when formulated with reinforcing fillers for electrical applications (circuit breaker insulation, encapsulation of capacitors and resistors, and coil forms).

### 4.5 Diallyl Phthalate

Diallyl phthalate (DAP) is the most widely used compound in the allylic family. The neat resin is a medium-viscosity liquid. These low-molecular-weight prepolymers can be reinforced and compression molded into highly cross-linked, completely cured products.

The most outstanding properties of DAP are excellent dimensional stability and high insulation resistance. In addition, DAP has high dielectric strength, excellent arc resistance, and chemical resistance.

**Uses.** DAP applications include electronic parts, electrical connectors, bases and housings. DAP is also used as a coating and impregnating material.

#### 4.6 Amino Resins

The two main members of the amino family of thermosets are the melamine and urea resins. They are prepared from the reaction of melamine and urea with formaldehyde. In general, these materials exhibit extreme hardness, scratch resistance, electrical resistance, and chemical resistance.

**Uses.** Melamine resins find use in colorful, rugged dinnerware, decorative laminates (countertops, tabletops, and furniture surfacing), electrical applications (switchboard panels, circuit breaker parts, arc barriers, and armature and slot wedges), and adhesives and coatings.

Urea resins are used in particleboard binders, decorative housings, closures, electrical parts, coatings, and paper and textile treatment.

### 5 GENERAL-PURPOSE ELASTOMERS

Elastomers are polymers that can be stretched substantially beyond their original length and can retract rapidly and forcibly to essentially their original dimensions (on release of the force).<sup>39,40</sup>

The optimum properties and/or economics of many rubbers are obtained through formulating with reinforcing agents, fillers, extending oils, vulcanizing agents, antioxidants, pigments, etc. End-use markets for formulated rubbers include automotive tire products (including tubes, retread applications, valve stems, and inner liners), adhesives, cements, caulks, sealants, latex foam products, hose (automotive, industrial, and consumer applications), belting (V-conveyor and trimming), footwear (heels, soles, slab stock, boots, and canvas), molded, extruded, and calendered products (athletic goods, flooring, gaskets, household products, O-rings, blown sponge, thread, and rubber sundries). A list of general-purpose elastomers and properties is summarized in Table 17.

### 6 SPECIALTY ELASTOMERS

Specialty rubbers offer higher performance over general-purpose rubbers and find use in more demanding applications.<sup>41</sup> They are more costly and hence are produced in smaller volumes. Properties and uses are summarized in Table 18.

### 1 INTRODUCTION

The development of composite materials and related design and manufacturing technologies is one of the most important advances in the history of materials. Composites are multifunctional materials having unprecedented mechanical and physical properties that can be tailored to meet the requirements of a particular application. Many composites also exhibit great resistance to high-temperature corrosion and oxidation and wear. These unique characteristics provide the mechanical engineer with design opportunities not possible with conventional monolithic (unreinforced) materials. Composites technology also makes possible the use of an entire class of solid materials, ceramics, in applications for which monolithic versions are unsuited because of their great strength scatter and poor resistance to mechanical and thermal shock. Further, many manufacturing processes for composites are well adapted to the fabrication of large, complex structures, which allows consolidation of parts, reducing manufacturing costs.

Composites are important materials that are now used widely, not only in the aerospace industry, but also in a large and increasing number of commercial mechanical engineering applications, such as internal combustion engines; machine components; thermal control and electronic packaging; automobile, train, and aircraft structures and mechanical components, such as brakes, drive shafts, flywheels, tanks, and pressure vessels; dimensionally stable components; process industries equipment requiring resistance to high-temperature corrosion, oxida-

tion, and wear; offshore and onshore oil exploration and production; marine structures; sports and leisure equipment; and biomedical devices.

It should be noted that biological structural materials occurring in nature are typically some type of composite. Common examples are wood, bamboo, bone, teeth, and shell. Further, use of artificial composite materials is not new. Straw-reinforced mud bricks were employed in biblical times. Using modern terminology, discussed later, this material would be classified as an organic fiber-reinforced ceramic matrix composite.

In this chapter, we consider the properties of reinforcements and matrix materials (Section 2) and the properties of composites (Section 3).

**1.1 Classes and Characteristics of Composite Materials**

There is no universally accepted definition of a composite material. For the purpose of this work, we consider a composite to be a material consisting of two or more distinct phases, bonded together.<sup>1</sup>

Solid materials can be divided into four categories: polymers, metals, ceramics, and carbon, which we consider as a separate class because of its unique characteristics. We find both reinforcements and matrix materials in all four categories. This gives us the ability to create a limitless number of new material systems with unique properties that cannot be obtained with any single monolithic material. Table 1 shows the types of material combinations now in use.

Composites are usually classified by the type of material used for the matrix. The four primary categories of composites are polymer matrix composites (PMCs), metal matrix composites (MMCs), ceramic matrix composites (CMCs), and carbon/carbon composites (CCCs). At this time, PMCs are the most widely used class of composites. However, there are important applications of the other types, which are indicative of their great potential in mechanical engineering applications.

Figure 1 shows the main types of reinforcements used in composite materials: aligned continuous fibers, discontinuous fibers, whiskers (elongated single crystals), particles, and numerous forms of fibrous architectures produced by textile technology, such as fabrics and braids. Increasingly, designers are using hybrid composites that combine different types of reinforcements to achieve more efficiency and to reduce cost.

A common way to represent fiber-reinforced composites is to show the fiber and matrix separated by a slash. For example, carbon fiber-reinforced epoxy is typically written “carbon/epoxy,” or, “C/Ep.” We represent particle reinforcements by enclosing them in parentheses followed by “p”; thus, silicon carbide (SiC) particle-reinforced aluminum appears as “(SiC)p/Al.”

**Table 1 Types of Composite Materials**

| Reinforcement | Matrix  |       |         |        |
|---------------|---------|-------|---------|--------|
|               | Polymer | Metal | Ceramic | Carbon |
| Polymer       | X       | X     | X       | X      |
| Metal         | X       | X     | X       | X      |
| Ceramic       | X       | X     | X       | X      |
| Carbon        | X       | X     | X       | X      |

Fig. 1 Reinforcement forms.

Composites are strongly heterogeneous materials; that is, the properties of a composite vary considerably from point to point in the material, depending on which material phase the point is located in. Monolithic ceramics and metallic alloys are usually considered to be homogeneous materials, to a first approximation.

Many artificial composites, especially those reinforced with fibers, are anisotropic, which means their properties vary with direction (the properties of isotropic materials are the same in every direction). This is a characteristic they share with a widely used natural fibrous composite, wood. As for wood, when structures made from artificial fibrous composites are required to carry load in more than one direction, they are used in laminated form.

Many fiber-reinforced composites, especially PMCs, MMCs, and CCCs, do not display plastic behavior as metals do, which makes them more sensitive to stress concentrations. However, the absence of plastic deformation does not mean that composites are brittle materials like monolithic ceramics. The heterogeneous nature of composites results in complex failure mechanisms that impart toughness. Fiber-reinforced materials have been found to produce durable, reliable structural components in countless applications. The unique characteristics of composite materials, especially anisotropy, require the use of special design methods.

## 1.2 Comparative Properties of Composite Materials

There are a large and increasing number of materials that fall in each of the four types of composites, making generalization difficult. However, as a class of materials, composites tend to have the following characteristics: high strength; high modulus; low density; excellent resistance to fatigue, creep, creep rupture, corrosion, and wear; and low coefficient of thermal expansion (CTE). As for monolithic materials, each of the four classes of composites has its own partic-

ular attributes. For example, CMCs tend to have particularly good resistance to corrosion, oxidation, and wear, along with high-temperature capability.

For applications in which both mechanical properties and low weight are important, useful figures of merit are specific strength (strength divided by specific gravity or density) and specific stiffness (stiffness divided by specific gravity or density). Figure 2 presents specific stiffness and specific tensile strength of conventional structural metals (steel, titanium, aluminum, magnesium, and beryllium), two engineering ceramics (silicon nitride and alumina), and selected composite materials. The composites are PMCs reinforced with selected contin-

**Fig. 2** Specific tensile strength (tensile strength divided by density) as a function of specific modulus (modulus divided by density) of composite materials and monolithic metals and ceramics.

uous fibers—carbon, aramid, E-glass, and boron—and an MMC, aluminum containing silicon carbide particles. Also shown is beryllium–aluminum, which can be considered a type of metal matrix composite, rather than an alloy, because the mutual solubility of the constituents at room temperature is low.

The carbon fibers represented in Figure 2 are made from several types of precursor materials: polyacrylonitrile (PAN), petroleum pitch, and coal tar pitch. Characteristics of the two types of pitch-based fibers tend to be similar but very different from those made from PAN. Several types of carbon fibers are represented: standard-modulus (SM) PAN, ultrahigh-strength (UHS) PAN, ultrahigh-modulus (UHM) PAN, and ultrahigh-modulus (UHM) pitch. These fibers are discussed in Section 2. It should be noted that there are dozens of different kinds of commercial carbon fibers, and new ones are continually being developed.

Because the properties of fiber-reinforced composites depend strongly on fiber orientation, fiber-reinforced polymers are represented by lines. The upper end corresponds to the axial properties of a unidirectional laminate, in which all the fibers are aligned in one direction. The lower end represents a quasi-isotropic laminate having equal stiffness and approximately equal strength characteristics in all directions in the plane of the fibers.

As Figure 2 shows, composites offer order-of-magnitude improvements over metals in both specific strength and stiffness. It has been observed that order-of-magnitude improvements in key properties typically produce revolutionary effects in a technology. Consequently, it is not surprising that composites are having such a dramatic influence in engineering applications.

In addition to their exceptional static strength properties, fiber-reinforced polymers also have excellent resistance to fatigue loading. Figure 3 shows how the number of cycles to failure ( $N$ ) varies with maximum stress ( $S$ ) for aluminum and selected unidirectional PMCs subjected to tension–tension fatigue. The ratio of minimum stress to maximum stress ( $R$ ) is 0.1. The composites consist of epoxy matrices reinforced with key fibers: aramid, boron, SM carbon, high-

**Fig. 3** Number of cycles to failure as a function of maximum stress for aluminum and unidirectional polymer matrix composites subjected to tension–tension fatigue with a stress ratio,  $R = 0.1$ . (From Ref. 2. Copyright ASTM. Reprinted with permission.)

strength (HS) glass, and E-glass. Because of their excellent fatigue resistance, composites have largely replaced metals in fatigue-critical aerospace applications, such as helicopter rotor blades. Composites also are being used in commercial fatigue-critical applications, such as automobile springs.

The outstanding mechanical properties of composite materials have been a key reason for their extensive use in structures. However, composites also have important physical properties, especially low, tailorable CTE and high-thermal conductivity, that are key reasons for their selection in an increasing number of applications.

Many composites, such as PMCs reinforced with carbon and aramid fibers, and silicon carbide particle-reinforced aluminum, have low CTEs, which are advantageous in applications requiring dimensional stability. By appropriate selection of reinforcements and matrix materials, it is possible to produce composites with near-zero CTEs.

Coefficient of thermal expansion tailorability provides a way to minimize thermal stresses and distortions that often arise when dissimilar materials are joined. For example, Fig. 4 shows how the CTE of silicon carbide particle-reinforced aluminum varies with particle content. By varying the amount of reinforcement, it is possible to match the CTEs of a variety of key engineering materials, such as steel, titanium, and alumina (aluminum oxide).

The ability to tailor CTE is particularly important in applications such as electronic packaging, where thermal stresses can cause failure of ceramic substrates, semiconductors, and solder joints.

**Fig. 4** Variation of coefficient of thermal expansion with particle volume fraction for silicon carbide particle-reinforced aluminum. (From Ref. 3, page 17. Copyright 1992 by TMS.)

Another unique and increasingly important property of some composites is their exceptionally high thermal conductivity. This is leading to increasing use of composites in applications for which heat dissipation is a key design consideration. In addition, the low densities of composites make them particularly advantageous in thermal control applications for which weight is important, such as laptop computers, avionics, and spacecraft components, such as radiators.

There are a large and increasing number of thermally conductive composites, which are discussed in Section 3. One of the most important types of reinforcements for these materials is pitch fibers. Figure 5 shows how thermal conductivity varies with electrical resistivity for conventional metals and carbon fibers. It can be seen that PAN-based fibers have relatively low thermal conductivities. However, pitch-based fibers with thermal conductivities more than twice that of copper are commercially available. These reinforcements also have very high stiffnesses and low densities. At the upper end of the carbon fiber curve are fibers made by chemical vapor deposition (CVD). Fibers made from another form of carbon, diamond, also have the potential for thermal conductivities in the range of 2000 W/m · K (1160 Btu/h · ft · °F).

1.3 Manufacturing Considerations

Composites also offer a number of significant manufacturing advantages over monolithic metals and ceramics. For example, fiber-reinforced polymers and ceramics can be fabricated in large, complex shapes that would be difficult or impossible to make with other materials. The ability to fabricate complex shapes allows consolidation of parts, which reduces machining and assembly costs. Some processes allow fabrication of parts to their final shape (net shape) or close to their final shape (near-net shape), which also produces manufacturing

Fig. 5 Thermal conductivity as a function of electrical resistivity of metals and carbon fibers (adapted from one of Amoco Performance Products).

cost savings. The relative ease with which smooth shapes can be made is a significant factor in the use of composites in aircraft and other applications for which aerodynamic considerations are important.

## 2 REINFORCEMENTS AND MATRIX MATERIALS

As discussed in Section 1, we divide solid materials into four classes: polymers, metals, ceramics, and carbon. There are reinforcements and matrix materials in each category. In this section, we consider the characteristics of key reinforcements and matrices.

There are important issues that must be discussed before we present constituent properties. The conventional materials used in mechanical engineering applications are primarily structural metals, for most of which there are industry and government specifications. The situation is very different for composites. Most reinforcements and matrices are proprietary materials for which there are no industry standards. This is similar to the current status of ceramics. The situation is further complicated by the fact that there are many test methods in use to measure mechanical and physical properties of reinforcements and matrix materials. As a result, there are often conflicting material property data in the usual sources, published papers, and manufacturers' literature. The data presented in this chapter represent a carefully evaluated distillation of information from many sources. The principal sources are listed in the bibliography and references. In view of the uncertainties discussed, the properties presented in this section should be considered approximate values.

Because of the large number of matrix materials and reinforcements, we are forced to be selective. Further, space limitations prevent presentation of a complete set of properties. Consequently, properties cited are room temperature values, unless otherwise stated.

### 2.1 Reinforcements

The four key types of reinforcements used in composites are continuous fibers, discontinuous fibers, whiskers (elongated single crystals), and particles (Fig. 1). Continuous, aligned fibers are the most efficient reinforcement form and are widely used, especially in high-performance applications. However, for ease of fabrication and to achieve specific properties, such as improved through-thickness strength, continuous fibers are converted into a wide variety of reinforcement forms using textile technology. Key among them at this time are two-dimensional and three-dimensional fabrics and braids.

#### Fibers

The development of fibers with unprecedented properties has been largely responsible for the great importance of composites and the revolutionary improvements in properties compared to conventional materials that they offer. The key fibers for mechanical engineering applications are glasses, carbons (also called graphites), several types of ceramics, and high-modulus organics. Most fibers are produced in the form of multifilament bundles called strands or ends in their untwisted forms, and yarns when twisted. Some fibers are produced as monofilaments, which generally have much larger diameters than strand filaments.

Table 2 presents properties of key fibers, which are discussed in the following subsections.

Fiber strength requires some discussion. Most of the key fibrous reinforcements are made of brittle ceramics or carbon. It is well known that the strengths of monolithic ceramics decrease with increasing material volume because of the increasing probability of finding strength-limiting flaws. This is called size effect. As a result of size effect, fiber strength typically decreases monotonically with increasing gauge length (and diameter). Flaw sensitivity also results in considerable strength scatter at a fixed test length. Consequently, there is no single value that characterizes fiber strength. This is also true of key organic reinforcements, such as aramid fibers. Consequently, the values presented in Table 2 should be considered approximate values and are useful primarily for comparative purposes. Note that, because unsupported fibers buckle under very low stresses, it is very difficult to measure their inherent compression strength, and these properties are almost never reported. Instead, composite compression strength is measured directly.

**Glass Fibers.** Glass fibers are used primarily to reinforce polymers. The leading types of glass fibers for mechanical engineering applications are E-glass and high-strength (HS) glass. E-glass fibers, the first major composite reinforcement, were originally developed for electrical insulation applications (that is the origin of the “E”). E-glass is, by many orders of magnitude, the most widely used of all fibrous reinforcements. The primary reasons for this are its low cost and early development compared to other fibers. Glass fibers are produced as multifilament bundles. Filament diameters range from 3–20  $\mu\text{m}$  (118–787  $\mu\text{in.}$ ). Table 2 presents representative properties of E-glass and HS glass fibers.

**Table 2 Properties of Key Reinforcing Fibers**

| Fiber                     | Density<br>[g/cm <sup>3</sup> (Pci)] | Axial<br>Modulus<br>[GPa (Msi)] | Tensile<br>Strength<br>[MPa (ksi)] | Axial<br>Coefficient of<br>Thermal<br>Expansion<br>[ppm/K<br>(ppm/°F)] | Axial<br>Thermal<br>Conductivity<br>[W/m · K] |

E-glass fibers have relatively low elastic moduli compared to other reinforcements. In addition, E-glass fibers are susceptible to creep and creep (stress) rupture. HS glass is stiffer and stronger than E-glass and has better resistance to fatigue and creep.

The thermal and electrical conductivities of glass fibers are low, and glass fiber-reinforced PMCs are often used as thermal and electrical insulators. The CTE of glass fibers is also low compared to most metals.

**Carbon (Graphite) Fibers.** Carbon fibers, commonly called graphite fibers in the United States, are used as reinforcements for polymers, metals, ceramics, and carbon. There are dozens of commercial carbon fibers, with a wide range of strengths and moduli. As a class of reinforcements, carbon fibers are characterized by high stiffness and strength, and low density and CTE. Fibers with tensile moduli as high as 895 GPa (130 Msi) and with tensile strengths of 7000 MPa (1000 ksi) are commercially available. Carbon fibers have excellent resistance to creep, stress rupture, fatigue, and corrosive environments, although they oxidize at high temperatures. Some carbon fibers also have extremely high thermal conductivities—many times that of copper. This characteristic is of considerable interest in electronic packaging and other applications where thermal control is important. Carbon fibers are the workhorse reinforcements in high-performance aerospace and commercial PMCs and some CMCs. Of course, as the name suggests, carbon fibers are also the reinforcements in carbon/carbon composites.

Most carbon fibers are highly anisotropic. Axial stiffness, tension and compression strength, and thermal conductivity are typically much greater than the corresponding properties in the radial direction. Carbon fibers generally have small, negative axial CTEs (which means that they get shorter when heated) and positive radial CTEs. Diameters of common reinforcing fibers, which are produced in the form of multifilament bundles, range from 4–10  $\mu\text{m}$  (160–390  $\mu\text{in.}$ ). Carbon fiber stress–strain curves tend to be nonlinear. Modulus increases under increasing tensile stress and decreases under increasing compressive stress.

Carbon fibers are made primarily from three key precursor materials: polyacrylonitrile (PAN), petroleum pitch, and coal tar pitch. Rayon-based fibers, once the primary CCC reinforcement, are far less common in new applications. Experimental fibers also have been made by chemical vapor deposition. Some of these have reported axial thermal conductivities as high as 2000 W/m · K, five times that of copper.

PAN-based materials are the most widely used carbon fibers. There are dozens on the market. Fiber axial moduli range from 235 GPa (34 Msi) to 590 GPa (85 Msi). They generally provide composites with excellent tensile and compressive strength properties, although compressive strength tends to drop off as modulus increases. Fibers having tensile strengths as high as 7 GPa (1 Msi) are available. Table 2 presents properties of three types of PAN-based carbon fibers and two types of pitch-based carbon fibers. The PAN-based fibers are standard modulus (SM), ultrahigh strength (UHS) and ultrahigh modulus (UHM). SM PAN fibers are the most widely used type of carbon fiber reinforcement. They are one of the first types commercialized and tend to be the least expensive. UHS PAN carbon fibers are the strongest type of another widely used class of carbon fiber,

usually called intermediate modulus (IM) because the axial modulus of these fibers falls between those of SM and modulus carbon fibers.

A key advantage of pitch-based fibers is that they can be produced with much higher axial moduli than those made from PAN precursors. For example, UHM pitch fibers with moduli as high as 895 GPa (130 Msi) are available. In addition, some pitch fibers, which we designate UHK, have extremely high axial thermal conductivities. There are commercial UHK fibers with a nominal axial thermal conductivity of 1100 W/m · K, almost three times that of copper. However, composites made from pitch-based carbon fibers generally are somewhat weaker in tension and shear, and much weaker in compression, than those using PAN-based reinforcements.

**Boron Fibers.** Boron fibers are primarily used to reinforce polymers and metals. Boron fibers are produced as monofilaments (single filaments) by chemical vapor deposition of boron on a tungsten wire or carbon filament, the former being the most widely used. They have relatively large diameters, 100–140  $\mu\text{m}$  (4000–5600  $\mu\text{in.}$ ), compared to most other reinforcements. Table 2 presents representative properties of boron fibers having a tungsten core and diameter of 140  $\mu\text{m}$ . The properties of boron fibers are influenced by the ratio of overall fiber diameter to that of the tungsten core. For example, fiber specific gravity is 2.57 for 100- $\mu\text{m}$  fibers and 2.49 for 140- $\mu\text{m}$  fibers.

**Fibers Based on Silicon Carbide.** Silicon-carbide-based fibers are primarily used to reinforce metals and ceramics. There are a number of commercial fibers based on silicon carbide. One type, a monofilament, is produced by chemical vapor deposition of high-purity silicon carbide on a carbon monofilament core. Some versions use a carbon-rich surface layer that serves as a reaction barrier. There are a number of multifilament silicon-carbide-based fibers made by pyrolysis of polymers. Some of these contain varying amounts of silicon, carbon and oxygen, titanium, nitrogen, zirconium, and hydrogen. Table 2 presents properties of selected silicon-carbide-based fibers.

**Fibers Based on Alumina.** Alumina-based fibers are primarily used to reinforce metals and ceramics. Like silicon-carbide-based fibers, they have a number of different chemical formulations. The primary constituents, in addition to alumina, are boria, silica, and zirconia. Table 2 presents properties of high-purity alumina fibers.

**Aramid Fibers.** Aramid, or aromatic, polyamide fibers are high-modulus organic reinforcements primarily used to reinforce polymers and for ballistic protection. There are a number of commercial aramid fibers produced by several manufacturers. Like other reinforcements, they are proprietary materials with different properties. Table 2 presents properties of one of the most widely used aramid fibers.

**High-Density Polyethylene Fibers.** High-density polyethylene fibers are primarily used to reinforce polymers and for ballistic protection. Table 2 presents properties of a common reinforcing fiber. The properties of high-density polyethylene tend to decrease significantly with increasing temperature, and they tend to creep significantly under load, even at low temperatures.

## 2.2 Matrix Materials

The four classes of matrix materials are polymers, metals, ceramics, and carbon. Table 3 presents representative properties of selected matrix materials in each category. As the table shows, the properties of the four types differ substantially. These differences have profound effects on the properties of the composites using them. In this section, we examine characteristics of key materials in each class.

### Polymer Matrix Materials

There are two major classes of polymers used as matrix materials: thermosets and thermoplastics. Thermosets are materials that undergo a curing process during part fabrication, after which they are rigid and cannot be reformed. Thermoplastics, on the other hand, can be repeatedly softened and reformed by application of heat. Thermoplastics are often subdivided into several types: amorphous, crystalline, and liquid crystal. There are numerous types of polymers in both classes. Thermosets tend to be more resistant to solvents and corrosive environments than thermoplastics, but there are exceptions to this rule. Resin selection is based on design requirements, as well as manufacturing and cost considerations. Table 4 presents representative properties of common matrix polymers.

Polymer matrices generally are relatively weak, low-stiffness, viscoelastic materials. The strength and stiffness of PMCs come primarily from the fiber phase. One of the key issues in matrix selection is maximum service temperature. The properties of polymers decrease with increasing temperature. A widely used measure of comparative temperature resistance of polymers is glass transition temperature ( $T_g$ ), which is the approximate temperature at which a polymer transitions from a relatively rigid material to a rubbery one. Polymers typically suffer significant losses in both strength and stiffness above their glass transition temperatures. New polymers with increasing temperature capability are continually being developed, allowing them to compete with a wider range of metals. For example, carbon fiber-reinforced polyimides have replaced titanium in some aircraft gas turbine engine parts.

An important consideration in selection of polymer matrices is their moisture sensitivity. Resins tend to absorb water, which causes dimensional changes and reduction of elevated temperature strength and stiffness. The amount of moisture absorption, typically measured as percent weight gain, depends on the polymer and relative humidity. Resins also desorb moisture when placed in a drier atmosphere. The rate of absorption and desorption depends strongly on temperature. The moisture sensitivity of resins varies widely; some are very resistant.

In a vacuum, resins outgas water and organic and inorganic chemicals, which can condense on surfaces with which they come in contact. This can be a problem in optical systems and can affect surface properties critical for thermal control, such as absorptivity and emissivity. Outgassing can be controlled by resin selection and baking out the component.

***Thermosetting Resins.*** The key types of thermosetting resins used in composites are epoxies, bismaleimides, thermosetting polyimides, cyanate esters, thermosetting polyesters, vinyl esters, and phenolics.

<sup>a</sup>Thermoset.  
<sup>b</sup>Thermoplastic.

Epoxies are the workhorse materials for airframe structures and other aerospace applications, with decades of successful flight experience to their credit. They produce composites with excellent structural properties. Epoxies tend to be rather brittle materials, but toughened formulations with greatly improved impact resistance are available. The maximum service temperature is affected by reduced elevated temperature structural properties resulting from water absorption. A typical airframe limit is about 120°C (250°F).

Bismaleimide resins are used for aerospace applications requiring higher temperature capabilities than can be achieved by epoxies. They are employed for temperatures of up to about 200°C (390°F).

Thermosetting polyimides are used for applications with temperatures as high as 250–290°C (500–550°F).

Cyanate ester resins are not as moisture sensitive as epoxies and tend to outgas much less. Formulations with operating temperatures as high as 205°C (400°F) are available.

Thermosetting polyesters are the workhorse resins in commercial applications. They are relatively inexpensive, easy to process, and corrosion resistant.

Vinyl esters are also widely used in commercial applications. They have better corrosion resistance than polyesters but are somewhat more expensive.

Phenolic resins have good high-temperature resistance and produce less smoke and toxic products than most resins when burned. They are used in applications such as aircraft interiors and offshore oil platform structures, for which fire resistance is a key design requirement.

**Thermoplastic Resins.** Thermoplastics are divided into three main classes: amorphous, crystalline, and liquid crystal. Polycarbonate, acrylonitrile–butadiene–styrene (ABS), polystyrene, polysulfone, and polyetherimide are amorphous materials. Crystalline thermoplastics include nylon, polyethylene, polyphenylene sulfide, polypropylene, acetal, polyethersulfone, and polyether etherketone (PEEK). Amorphous thermoplastics tend to have poor solvent resistance. Crystalline materials tend to be better in this respect. Relatively inexpensive thermoplastics such as nylon are extensively used with chopped E-glass fiber reinforcements in countless injection-molded parts. There are an increasing number of applications using continuous fiber-reinforced thermoplastics.

## Metals

The metals initially used for MMC matrix materials generally were conventional alloys. Over time, however, many special matrix materials tailored for use in composites have been developed. The key metallic matrix materials used for structural MMCs are alloys of aluminum, titanium, iron, and intermetallic compounds, such as titanium aluminides. However, many other metals have been used as matrix materials, such as copper, lead, magnesium, cobalt, silver, and superalloys. The *in situ* properties of metals in a composite depend on the manufacturing process and, because metals are elastic–plastic materials, the history of mechanical stresses and temperature changes to which they are subjected.

## Ceramic Matrix Materials

The key ceramics used as CMC matrices are silicon carbide, alumina, silicon nitride, mullite, and various cements. The properties of ceramics, especially

strength, are even more process sensitive than those of metals. In practice, it is very difficult to determine the *in situ* properties of ceramic matrix materials in a composite.

As discussed earlier, in the section on fiber properties, ceramics are very flaw sensitive, resulting in a decrease in strength with increasing material volume, a phenomenon called “size effect.” As a result, there is no single value that describes the tensile strength of ceramics. In fact, because of the very brittle nature of ceramics, it is difficult to measure tensile strength, and flexural strength (often called modulus of rupture) is typically reported. It should be noted that flexural strength is also dependent on specimen size and is generally much higher than that of a tensile coupon of the same dimensions. In view of the great difficulty in measuring a simple property like tensile strength, which arises from their flaw sensitivity, it is not surprising that monolithic ceramics have had limited success in applications where they are subjected to significant tensile stresses.

The fracture toughness of ceramics is typically in the range of  $3\text{--}6 \text{ MPa} \cdot \text{m}^{1/2}$ . Those of transformation-toughened materials are somewhat higher. For comparison, the fracture toughnesses of structural metals are generally greater than  $20 \text{ MPa} \cdot \text{m}^{1/2}$ .

### Carbon Matrix Materials

Carbon is a remarkable material. It includes materials ranging from lubricants to diamonds and structural fibers. The forms of carbon matrices resulting from the various carbon/carbon manufacturing processes tend to be rather weak, brittle materials. Some forms have very high thermal conductivities. As for ceramics, *in situ* matrix properties are difficult to measure.

## 3 PROPERTIES OF COMPOSITE MATERIALS

There are a large and increasing number of materials in all four classes of composites: polymer matrix composites (PMCs), metal matrix composites (MMCs), ceramic matrix composites (CMCs), and carbon/carbon composites (CCCs). In this section, we present mechanical and physical properties of some of the key materials in each class.

Initially, the excellent mechanical properties of composites was the main reason for their use. However, there are an increasing number of applications for which the unique and tailorable physical properties of composites are key considerations. For example, the extremely high thermal conductivity and tailorable coefficient of thermal expansion (CTE) of some composite material systems are leading to their increasing use in electronic packaging. Similarly, the extremely high stiffness, near-zero CTE, and low density of carbon fiber-reinforced polymers have made these composites the materials of choice in spacecraft structures.

Composites are complex, heterogeneous, and often anisotropic material systems. Their properties are affected by many variables, including *in situ* constituent properties; reinforcement form, volume fraction and geometry; properties of the interphase, the region where the reinforcement and matrix are joined (also called the interface); and void content. The process by which the composite is made affects many of these variables. The same matrix material and reinforcements, when combined by different processes, may result in composites with very different properties.

Several other important things must be kept in mind when considering composite properties. For one, most composites are proprietary material systems made by proprietary processes. There are few industry or government specifications for composites, as there are for many monolithic structural metals. However, this is also the case for many monolithic ceramics and polymers, which are widely used engineering materials. Despite their inherently proprietary nature, some widely used composite materials made by a number of manufacturers have similar properties. A notable example is standard-modulus (SM) carbon fiber-reinforced epoxy.

Another critical issue is that properties are sensitive to the test methods by which they are measured, and there are many different test methods used throughout the industry. Further, test results are very sensitive to the skill of the technician performing the test. Because of these factors, it is very common to find significant differences in reported properties of what is nominally the same composite material.

In Section 2, we discussed the issue of size effect, which is the decrease in strength with increasing material volume that is observed in monolithic ceramics key reinforcing fibers. There is some evidence, suggestive but not conclusive, of size effects in composite strength properties, as well. However, if composite strength size effects exist at all, they are much less severe than for fibers by themselves. The reason is that the presence of a matrix results in very different failure mechanisms. However, until the issues are resolved definitively, caution should be used in extrapolating strength data from small coupons to large structures, which may have volumes many orders of magnitude greater.

As mentioned earlier, the properties of composites are very sensitive to reinforcement form, volume fraction, and geometry. This is illustrated in Table 5, which presents the properties of several common types of E-glass fiber-reinforced polyester composites. The reinforcement forms are discontinuous fibers, woven roving (a heavy fabric), and straight, parallel continuous fibers. As we shall see, discontinuous reinforcement is not as efficient as continuous. However, discontinuous fibers allow the composite material to flow during processing, facilitating fabrication of complex molded parts.

The composites using discontinuous fibers are divided into three categories. One is bulk molding compound (BMC), also called dough molding compound, in which fibers are relatively short, about 3–12 mm, and are nominally randomly

**Table 5 Effect of Fiber Form and Volume Fraction on Mechanical Properties of E-Glass-Reinforced Polyester<sup>4</sup>**

oriented in three dimensions. BMC also has a very high loading of mineral particles, such as calcium carbonate, which are added for a variety of reasons: to reduce dimensional changes from resin shrinkage, to obtain a smooth surface, and to reduce cost, among others. Because it contains both particulate and fibrous reinforcement, BMC can be considered a type of hybrid composite.

The second type of composite is chopped strand mat (CSM), which contains discontinuous fibers, typically about 25 mm long, nominally randomly oriented in two directions. The third material is sheet molding compound (SMC), which contains chopped fibers 25–50 mm in length, also nominally randomly oriented in two dimensions. Like BMC, SMC also contains particulate mineral fillers, such as calcium carbonate and clay.

The first thing to note in comparing the materials in Table 5 is that fiber content, here presented in the form of weight percent, differs considerably for the four materials. This is significant, because, as discussed in Section 2, the strength and stiffness of polyester and most polymer matrices is considerably lower than those of E-glass, carbon, and other reinforcing fibers. Composites reinforced with randomly oriented fibers tend to have lower volume fractions than those made with aligned fibers or fabrics. There is a notable exception to this. Some composites with discontinuous-fiber reinforcement are made by chopping up composites reinforced with aligned continuous fibers or fabrics that have high-fiber contents.

Examination of Table 5 shows that the modulus of SMC is considerably greater than that of CSM, even though both have the same fiber content. This is because SMC also has particulate reinforcement. Note, however, that although the particles improve modulus, they do not increase strength. This is generally the case for particle-reinforced polymers, but, as we will see later, particles often do enhance the strengths of MMCs and CMCs, as well as their moduli.

We observe that the modulus of the BMC composite is greater than that of CSM and SMC, even though the former has a much lower fiber content. Most likely, this results from the high-mineral content and also the possibility that the fibers are oriented in the direction of test, and are not truly random. Many processes, especially those involving material flow, tend to orient fibers in one or more preferred directions. If so, then one would find the modulus of the BMC to be much lower than the one presented in the table if measured in other directions. This illustrates one of the limitations of using discontinuous fiber reinforcement: it is often difficult to control fiber orientation.

The moduli and strengths of the composites reinforced with fabrics and aligned fibers are much higher than those with discontinuous fibers, when the former two types of materials are tested parallel to fiber directions. For example, the tensile strength of woven roving is more than twice that of CSM. The properties presented are measured parallel to the warp direction of the fabric (the warp direction is the lengthwise direction of the fabric). The elastic and strength properties in the fill direction, perpendicular to the warp, typically are similar to, but somewhat lower than, those in the warp direction. Here, we assume that the fabric is “balanced,” which means that the number of fibers in the warp and fill directions per unit length are approximately equal. Note, however, that the elastic modulus, tensile strength, and compressive strength at 45° to the warp and fill directions of a fabric are much lower than the corresponding values in

the warp and fill directions. This is discussed further in the sections that cover design.

As Table 5 shows, the axial modulus and tensile strength of the unidirectional composite are much greater than those of the fabric. However, the modulus and strength of the unidirectional composite in the transverse direction are considerably lower than the corresponding axial properties. Further, the transverse strength is considerably lower than that of SMC and CSM. In general, the strength of PMCs is weak in directions for which there are no fibers. The low transverse moduli and strengths of unidirectional PMCs are commonly overcome by use of laminates with fibers in several directions. Low through-thickness strength can be improved by use of three-dimensional reinforcement forms. Often, the designer simply assures that through-thickness stresses are within the capability of the material.

In this section, we present representative mechanical and physical properties of key composite materials of interest for a broad range of mechanical engineering applications. The properties represent a distillation of values from many sources. Because of space limitations, it is necessary to be selective in our choice of materials and properties presented. It is simply not possible to present a complete set of data that will cover every possible application. As discussed earlier, there are many textile forms, such as woven fabrics, used as reinforcements. However, we concentrate on aligned, continuous fibers because they produce the highest strength and stiffness. To do a thorough evaluation of composites, the design engineer should consider alternative reinforcement forms. Unless otherwise stated, room temperature property values are presented. We consider mechanical properties in Section 3.1 and physical properties in Section 3.2.

### **3.1 Mechanical Properties of Composite Materials**

In this section, we consider mechanical properties of key PMCs, MMCs, CMCs, and CCCs that are of greatest interest for mechanical engineering applications.

#### **Mechanical Properties of Polymer Matrix Composites**

As discussed earlier, polymers are relatively weak, low-stiffness materials. To obtain materials with mechanical properties that are acceptable for structural applications, it is necessary to reinforce them with continuous or discontinuous fibers. The addition of ceramic or metallic particles to polymers results in materials that have increased modulus, but, as a rule, strength typically does not increase significantly, and may actually decrease. However, there are many particle-reinforced polymers used in electronic packaging, primarily because of their physical properties. For these applications, ceramic particles, such as alumina, aluminum nitride, boron nitride, and even diamond, are added to obtain an electrically insulating material with higher thermal conductivity and lower CTE than the monolithic base polymer. Metallic particles such as silver and aluminum are added to create materials that are both electrically and thermally conductive. These materials have replaced lead-based solders in many applications. There are also magnetic composites made by incorporating ferrous or permanent magnet particles in various polymers. A common example is magnetic tape used to record audio and video.

We focus on composites reinforced with continuous fibers because they are the most efficient structural materials. Table 6 presents room temperature mechanical properties of unidirectional polymer matrix composites reinforced with key fibers: E-glass, aramid, boron, standard-modulus (SM) PAN (polyacrylonitrile) carbon, ultrahigh-strength (UHS) PAN carbon, ultrahigh-modulus (UHM) PAN carbon, ultrahigh-modulus (UHM) pitch carbon, and ultrahigh-thermal conductivity (UHK) pitch carbon. We assume that the fiber volume fraction is 60%, a typical value. As discussed in Section 2, UHS PAN carbon is the strongest type of intermediate-modulus (IM) carbon fiber.

The properties presented in Table 6 are representative of what can be obtained at room temperature with a well-made PMC employing an epoxy matrix. Epoxies are widely used, provide good mechanical properties, and can be considered a reference matrix material. Properties of composites using other resins may differ from these, and have to be examined on a case-by-case basis.

The properties of PMCs, especially strengths, depend strongly on temperature. The temperature dependence of polymer properties differs considerably. This is also true for different epoxy formulations, which have different cure and glass transition temperatures. Some polymers, such as polyimides, have good elevated temperature properties that allow them to compete with titanium. There are aircraft gas turbine engine components employing polyimide matrices that see service temperatures as high as 290°C (550°F). Here again, the effect of temperature on composite properties has to be considered on a case-by-case basis.

The properties shown in Table 6 are axial, transverse and shear moduli, Poisson's ratio, tensile and compressive strengths in the axial and transverse directions, and inplane shear strength. The Poisson's ratio presented is called the major Poisson's ratio. It is defined as the ratio of the magnitude of transverse strain divided by axial strain when the composite is loaded in the axial direction. Note that transverse moduli and strengths are much lower than corresponding axial values.

As discussed in Section 2, carbon fibers display nonlinear stress-strain behavior. Their moduli increase under increasing tensile stress and decrease under increasing compressive stress. This makes the method of calculating modulus critical. Various tangent and secant definitions are used throughout the industry, contributing to the confusion in reported properties. The values presented in Table 6, which are approximate, are based on tangents to the stress-strain curves at the origin. Using this definition, tensile and compressive moduli are usually very similar. However, this is not the case for moduli using various secant definitions. Using these definitions typically produces compression moduli that are significantly lower than tension moduli.

Because of the low transverse strengths of unidirectional laminates, they are rarely used in structural applications. The design engineer uses laminates with layers in several directions to meet requirements for strength, stiffness, buckling, and so on. There are an infinite number of laminate geometries that can be selected. For comparative purposes, it is useful to consider quasi-isotropic laminates, which have the same elastic properties in all directions in the plane. Laminates are quasi-isotropic when they have the same percentage of layers every  $180/n^\circ$ , where  $n \geq 3$ . The most common quasi-isotropic laminates have layers that repeat every  $60^\circ$ ,  $45^\circ$ , or  $30^\circ$ . We note, however, that strength prop-

| UHK carbon (pitch)                                                                 | 480 (70)                  | 9 (1.3)                        | 4.1 (0.6)                         | 0.25            | 900 (130)                          | 20 (3)                                  | 280 (40)                               | 100 (15)                                    | 41 (6)                             |

erties in the plane are not isotropic for these laminates, although they tend to become more uniform as the angle of repetition becomes smaller.

Table 7 presents the mechanical properties of quasi-isotropic laminates. Note that the moduli and strengths are much lower than the axial properties of unidirectional laminates made of the same material. In most applications, laminate geometry is such that the maximum axial modulus and tensile and compressive strengths fall somewhere between axial unidirectional and quasi-isotropic values.

The tension–tension fatigue behavior of unidirectional composites, discussed in Section 1, is one of their great advantages over metals (Fig. 6). In general the tension–tension  $S$ – $N$  curves (curves of maximum stress plotted as a function of cycles to failure) of PMCs reinforced with carbon, boron, and aramid fibers are relatively flat. Glass-fiber-reinforced composites show a greater reduction in strength with increasing number of cycles. Still, PMCs reinforced with HS glass are widely used in applications for which fatigue resistance is a critical design consideration, such as helicopter rotors.

Metals are more likely to fail in fatigue when subjected to fluctuating tensile rather than compressive load. This is because they tend to fail by crack propagation under fatigue loading. However, the failure modes in composites are very different and more complex. One consequence is that composites tend to be more susceptible to fatigue failure when loaded in compression. Figure 6 shows the cycles to failure as a function of maximum stress for carbon-fiber-reinforced epoxy laminates subjected to tension–tension and compression–compression fatigue. The laminates have 60% of their layers oriented at  $0^\circ$ , 20% at  $+45^\circ$ , and 20% at  $-45^\circ$ . They are subjected to a fluctuating load in the  $0^\circ$  direction. The ratios of minimum stress-to-maximum stress ( $R$ ) for tensile and compressive fatigue are 0.1 and 10, respectively. We observe that the reduction in strength is much greater for compression–compression fatigue. However, the composite compressive fatigue strength at  $10^7$  cycles is still considerably greater than the corresponding tensile value for aluminum.

Polymer matrix composites reinforced with carbon and boron are very resistant to deformation and failure under sustained static load when they are loaded in a fiber-dominated direction. (These phenomena are called creep and creep rupture, respectively.) The creep and creep rupture behavior of aramid is not quite as good. Glass fibers display significant creep, and creep rupture is an important design consideration. Polymers are viscoelastic materials that typically display significant creep when they are not constrained with fibers. Therefore, creep should be considered when composites are subjected to significant stresses in matrix-dominated directions, such as the laminate through-thickness direction.

### **Mechanical Properties of Metal Matrix Composites**

Monolithic metallic alloys are the most widely used materials in mechanical engineering applications. By reinforcing them with continuous fibers, discontinuous fibers, whiskers and particles, we create new materials with enhanced or modified properties, such as higher strength and stiffness, better wear resistance, lower CTE, and so on. In some cases, the improvements are dramatic.

The greatest increases in strength and modulus are achieved with continuous fibers. However, the relatively high cost of many continuous reinforcing fibers used in MMCs has limited the application of these materials. The most widely

**Fig. 6** Cycles to failure as a function of maximum stress for carbon-fiber-reinforced epoxy laminates loaded in tension-tension ( $R = 0.1$ ) and compression-compression ( $R = -10$ ) fatigue (after Ref. 5).

used MMCs are reinforced with discontinuous fibers or particles. This may change as new, lower cost continuous fibers and processes are developed and as cost drops with increasing production volume.

**Continuous Fiber-Reinforced MMCs.** One of the major advantages of MMCs reinforced with continuous fibers over PMCs is that many, if not most, unidirectional MMCs have much greater transverse strengths, which allow them to be used in a unidirectional configuration. Table 8 presents representative mechanical properties of selected unidirectional MMCs reinforced with continuous fibers corresponding to a nominal fiber volume fraction of 50%. The values represent a distillation obtained from numerous sources. In general, the axial moduli of the composites are much greater than those of the monolithic base metals used for the matrices. However, MMC transverse strengths are typically lower than those of the parent matrix materials.

**Mechanical Properties of Discontinuous Fiber-Reinforced MMCs.** One of the primary mechanical engineering applications of discontinuous fiber-reinforced MMCs is in internal combustion engine components. Fibers are added primarily to improve the wear resistance and elevated temperature strength and fatigue properties of aluminum. The improvement in wear resistance eliminates the need for cast-iron sleeves in engine blocks and cast-iron insert rings in pistons. Fiber-reinforced aluminum composites also have higher thermal conductivities than cast iron and, when fiber volume fractions are relatively low, their CTEs are closer to that of unreinforced aluminum, reducing thermal stresses.

The key reinforcements used in internal combustion engine components to increase wear resistance are discontinuous alumina and alumina-silica fibers. In one application, Honda Prelude engine blocks, carbon fibers are combined with

alumina to tailor both wear resistance and coefficient of friction of cylinder walls. Wear resistance is not an inherent property, so that there is no single value that characterizes a material. However, in engine tests, it was found that ring groove wear for an alumina fiber-reinforced aluminum piston was significantly less than that for one with a cast-iron insert.

***Mechanical Properties of Particle-Reinforced MMCs.*** Particle-reinforced metals are a particularly important class of MMCs for engineering applications. A wide range of materials fall into this category, and a number of them have been used for many years. An important example is a material consisting of tungsten carbide particles embedded in a cobalt matrix that is used extensively in cutting tools and dies. This composite, often referred to as a cermet, cemented carbide, or simply, but incorrectly, “tungsten carbide,” has much better fracture toughness than monolithic tungsten carbide, which is a brittle ceramic material. Another interesting MMC, tungsten carbide particle-reinforced silver, is a key circuit breaker contact pad material. Here, the composite provides good electrical conductivity and much greater hardness and wear resistance than monolithic silver, which is too soft to be used in this application. Ferrous alloys reinforced with titanium carbide particles, discussed in the next subsection, have been used for many years in commercial applications. Compared to the monolithic base metals, they offer greater wear resistance and stiffness and lower density.

***Mechanical Properties of Titanium Carbide Particle-Reinforced Steel.*** A number of ferrous alloys reinforced with titanium carbide particles have been used in mechanical system applications for many years. To illustrate the effect of the particulate reinforcements, we consider a particular composite consisting of austenitic stainless steel reinforced with 45% by volume of titanium carbide particles. The modulus of the composite is 304 GPa (44 Msi) compared to 193 GPa (28 Msi) for the monolithic base metal. The specific gravity of the composite is 6.45, about 20% lower than that of monolithic matrix, 8.03. The specific stiffness of the composite is almost double that of the unreinforced metal.

***Mechanical Properties of Silicon Carbide Particle-Reinforced Aluminum.*** Aluminum reinforced with silicon carbide particles is one of the most important of the newer types of MMCs. A wide range of materials fall into this category. They are made by a variety of processes. Properties depend on the type of particle, particle volume fraction, matrix alloy, and the process used to make them. Table 9 shows how representative composite properties vary with particle volume fraction. In general, as particle volume fraction increases, modulus and yield strength increase and fracture toughness and tensile ultimate strain decrease. Particle reinforcement also improves short-term elevated temperature strength properties and fatigue resistance.

***Mechanical Properties of Alumina Particle-Reinforced Aluminum.*** Alumina particles are used to reinforce aluminum as an alternative to silicon carbide particles because they do not react as readily with the matrix at high temperatures and are less expensive. Consequently, alumina-reinforced composites can be used in a wider range of processes and applications. However, the stiffness and thermal conductivity of alumina are lower than the corresponding properties of silicon carbide, and these characteristics are reflected in somewhat lower values for composite properties.

**Table 9 Mechanical Properties of Silicon Carbide Particle-Reinforced Aluminum**

**Mechanical Properties of Ceramic Matrix Composites**

Ceramics, in general, are characterized by high stiffness and hardness, resistance to wear, corrosion and oxidation, and high-temperature operational capability. However, they also have serious deficiencies that have severely limited their use in applications that are subjected to significant tensile stresses. Ceramics have very low fracture toughness, which makes them very sensitive to the presence of small flaws. This results in great strength scatter and poor resistance to thermal and mechanical shock. Civil engineers recognized this deficiency long ago and, in construction, ceramic materials like stone and concrete are rarely used to carry tensile loads. In concrete, this function has been relegated to reinforcing bars made of steel or, more recently, PMCs. An important exception has been in lightly loaded structures where dispersed reinforcing fibers of asbestos, steel, glass, and carbon allow modest tensile stresses to be supported.

In CMCs, fibers, whiskers, and particles are combined with ceramic matrices to improve fracture toughness, which reduces strength scatter and improves thermal and mechanical shock resistance. By a wide margin, the greatest increases in fracture resistance result from the use of continuous fibers. Table 10 compares fracture toughnesses of structural metallic alloys with those of monolithic ceramics and CMCs reinforced with whiskers and continuous fibers. The low fracture toughness of monolithic ceramics gives rise to very small critical flaw sizes. For example, the critical flaw sizes for monolithic ceramics corresponding to a failure stress of 700 MPa (about 100 ksi) are in the range of 20–80  $\mu\text{m}$ . Flaws of this size are difficult to detect with conventional nondestructive techniques.

The addition of continuous fibers to ceramics can, if done properly, significantly increase the effective fracture toughness of ceramics. For example, as Table 10 shows, addition of silicon carbide fibers to a silicon carbide matrix results in a CMC having a fracture toughness in the range of aluminum alloys.

The addition of continuous fibers to a ceramic matrix also changes the failure mode. Figure 7 compares the tensile stress–strain curves for a typical monolithic ceramic and a conceptual continuous fiber-reinforced CMC. The monolithic material has a linear stress–strain curve and fails catastrophically at a low strain level. However, the CMC displays a nonlinear stress–strain curve with much more area under the curve, indicating that more energy is absorbed during failure

**Table 10 Fracture Toughness of Structural Alloys, Monolithic Ceramics, and Ceramic Matrix Composites**

| Matrix          | Reinforcement                     | Fracture Toughness<br>MPa m <sup>1/2</sup> |
|-----------------|-----------------------------------|--------------------------------------------|
| Aluminum        | none                              | 30–45                                      |
| Steel           | none                              | 40–65 <sup>a</sup>                         |
| Alumina         | none                              | 3–5                                        |
| Silicon carbide | none                              | 3–4                                        |
| Alumina         | Zirconia particles <sup>b</sup>   | 6–15                                       |
| Alumina         | Silicon carbide whiskers          | 5–10                                       |
| Silicon carbide | Continuous silicon carbide fibers | 25–30                                      |

<sup>a</sup>The toughness of some alloys can be much higher.

<sup>b</sup>Transformation-toughened.

Fig. 7 Stress-strain curves for a monolithic ceramic and ceramic matrix composite reinforced with continuous fibers.

and that the material has a less catastrophic failure mode. The fiber-matrix interphase properties must be carefully tailored and maintained over the life of the composite to obtain this desirable behavior.

Although the CMC stress-strain curve looks, at first, like that of an elastic-plastic metal, this is deceiving. The departure from linearity in the CMC results from internal damage mechanisms, such as the formation of microcracks in the matrix. The fibers bridge the cracks, preventing them from propagating. However, the internal damage is irreversible. As the figure shows, the slope of the stress-strain curve during unloading and subsequent reloading is much lower than that representing initial loading. For an elastic-plastic material, the slopes of the unloading and reloading curves are parallel to the initial elastic slope.

There are numerous CMCs at various stages of development. One of the most mature types consists of a silicon carbide matrix reinforced with fabric woven of silicon-carbide-based fibers. These composites are commonly referred to as SiC/SiC. We consider one version. Because the modulus of the particular silicon-carbide-based fibers used in this material is lower than that of pure silicon carbide, the modulus of the composite, about 210 GPa (30 Msi), is lower than that of monolithic silicon carbide, 440 GPa (64 Msi). The flexural strength of the composite parallel to the fabric warp direction, about 300 MPa (44 ksi), is maintained to a temperature of at least 1100°C for short times. Long-term strength behavior depends on degradation of the fibers, matrix, and interphase. Because of the continuous fiber reinforcement, SiC/SiC displays excellent resistance to severe thermal shock.

### Mechanical Properties of Carbon/Carbon Composites

Carbon/carbon composites consist of continuous and discontinuous carbon fibers embedded in carbon matrices. As for other composites, there are a wide range of materials that fall in this category. The variables affecting properties include type of fiber, reinforcement form, and volume fraction and matrix characteristics.

Historically, CCCs were first used because of their excellent resistance to high-temperature ablation. Initially, strengths and stiffnesses were low, but these properties have steadily increased over the years. CCCs are an important class of materials in high-temperature applications such as aircraft brakes, rocket nozzles, racing car brakes and clutches, glass-making equipment, and electronic packaging, among others.

One of the most significant limitations of CCCs is oxidation, which begins at a temperature threshold of approximately 370°C (700°F) for unprotected materials. Addition of oxidation inhibitors raises the threshold substantially. In inert atmospheres, CCCs retain their properties to temperatures as high as 2800°C (5000°F).

Carbon matrices are typically weak, brittle, low-stiffness materials. As a result, transverse and through-thickness elastic moduli and strength properties of unidirectional CCCs are low. Because of this, two-dimensional and three-dimensional reinforcement forms are commonly used. In the direction of fibrous reinforcement, it is possible to obtain moduli as high as 340 GPa (50 Msi), tensile strengths as high as 700 MPa (100 ksi), and compressive strengths as high as 800 MPa (110 ksi). In directions orthogonal to fiber directions, elastic moduli are in the range of 10 MPa (1.5 ksi), tensile strengths 14 MPa (2 ksi), and compressive strengths 34 MPa (5 ksi).

### 3.2 Physical Properties of Composite Materials

Material physical properties are critical for many applications. In this category, we include, among others, density, CTE, thermal conductivity, and electromagnetic characteristics. In this section, we concentrate on the properties of most general interest to mechanical engineers: density, CTE, and thermal conductivity.

Thermal control is a particularly important consideration in electronic packaging because failure rates of semiconductors increase exponentially with temperature. Since conduction is an important method of heat removal, thermal conductivity is a key material property. For many applications, such as spacecraft, aircraft, and portable systems, weight is also an important factor, and consequently, material density is also significant. A useful figure of merit is specific thermal conductivity, defined as thermal conductivity divided by density. Specific thermal conductivity is analogous to specific modulus and specific strength.

In addition to thermal conductivity and density, CTE is also of great significance in many applications. For example, semiconductors and ceramic substrates used in electronics are brittle materials with coefficients of expansion in the range of about 3–7 ppm/K. Semiconductors and ceramic substrates are typically attached to supporting components, such as packages, printed circuit boards (PCBs), and heat sinks with solder or an adhesive. If the CTE of the supporting material is significantly different from that of the ceramic or semiconductor, thermal stresses arise when the assembly is subjected to a change in temperature. These stresses can result in failure of the components or the joint between them.

A great advantage of composites is that there are an increasing number of material systems that combine high thermal conductivity with tailorable CTE, low density, and excellent mechanical properties. Composites can truly be called multifunctional materials.

The key composite materials of interest for thermal control are PMCs, MMCs, and CCCs reinforced with ultrahigh-thermal conductivity (UHK) carbon fibers, which are made from pitch; silicon carbide particle-reinforced aluminum; beryllium oxide particle-reinforced beryllium; and diamond particle-reinforced aluminum and copper. There also are a number of other special CCCs developed specifically for thermal control applications.

Table 11 presents physical properties of a variety of unidirectional composites reinforced with UHK carbon fibers, along with those of monolithic copper and 6063 aluminum for comparison. Unidirectional composites are useful for directing heat in a particular direction. The particular fibers represented have a nominal axial thermal conductivity of  $1100 \text{ W/m} \cdot \text{K}$ . Predicted properties are shown for four matrices: epoxy, aluminum, copper, and carbon. Typical reinforcement volume fractions (V/O) are assumed. As Table 11 shows, the specific axial thermal conductivities of the composites are significantly greater than those of aluminum and copper.

Figure 8 presents thermal conductivity as a function of CTE for various materials used in electronic packaging. Materials shown include silicon (Si) and gallium arsenide (GaAs) semiconductors; alumina ( $\text{Al}_2\text{O}_3$ ), beryllium oxide (BeO), and aluminum nitride (AlN) ceramic substrates; and monolithic aluminum, beryllium, copper, silver, and Kovar, a nickel–iron alloy. Other monolithic materials included are diamond and pyrolytic graphite, which have very high thermal conductivities in some forms. The figure also presents metal–metal composites, such as copper–tungsten (Cu–W), copper–molybdenum (Cu–Mo), beryllium–aluminum (Be–Al), aluminum–silicon (Al–Si), and Silvar, which contains silver and a nickel–iron alloy. The latter materials can be considered composites rather than true alloys because the two components have low solubility and appear as distinct phases at room temperature.

As Figure 8 shows, aluminum, copper, and silver have relatively high thermal conductivities but have CTEs much greater than desirable for most electronic packaging applications. By combining these metals with various reinforcements, it is possible to create new materials having CTEs isotropic in two dimensions (quasi-isotropic) or three dimensions in the desired range. The figure shows a number of composites: copper reinforced with UHK carbon fibers (C/Cu), aluminum reinforced with UHK carbon fibers (C/Al), carbon reinforced with UHK carbon fibers (C/C), epoxy reinforced with UHK carbon fibers (C/Ep), aluminum reinforced with silicon carbide particles [(SiC)p/Al], beryllium oxide particle-reinforced beryllium [(BeO)p/Be], diamond particle-reinforced copper [(Diamond)p/Cu], and E-glass fiber-reinforced epoxy (E-glass/Ep). With the exception of E-glass/Ep, C/Ep, and C/C, all of the composites have some configurations with CTEs in the desired range. The thermal conductivities of the composites presented are generally similar to, or better than, that of aluminum, while their CTEs are much closer to the goal range of  $3\text{--}7 \text{ ppm/K}$ . E-glass/Ep is an exception.

Note that although the CTEs of C/Ep and C/C are lower than desired for electronic packaging applications, the differences between their CTEs and those of ceramics and semiconductors are much less than the differences for aluminum and copper. Consequently, use of the composites can result in lower thermal stresses for a given temperature change.

Fig. 8 Thermal conductivity as a function of coefficient of thermal expansion for selected monolithic materials and composites used in electronic packaging.

The physical properties of the materials shown in Figure 8 and others are presented in Table 12.

The advantages of composites are even greater than those of conventional packaging materials when weight is considered. Figure 9 presents the specific thermal conductivities and CTEs of the materials appearing in Figure 8. Here, we find order-of-magnitude improvements. As discussed earlier, when a critical property is increased by an order of magnitude it tends to have a revolutionary effect on technology. Several composites demonstrate this level of improvement; as a result, composites are being used in an increasing number of electronic packaging and thermal control applications.

Table 12 Physical Properties of Isotropic and Quasi-Isotropic Composites and Monolithic Materials Used in Electronic Packaging

Fig. 9 Specific thermal conductivity (thermal conductivity divided by specific gravity) for selected monolithic materials and composites used in electronic packaging.

### Physical Properties of Polymer Matrix Composites

Table 13 presents physical properties of the polymer matrix composites discussed in Section 3.1. A fiber volume fraction of 60% is assumed. The densities of all of the materials are considerably lower than that of aluminum, and some are lower than that of magnesium. This reflects the low densities of both fibers and matrix materials. The low densities of most polymers give PMCs a significant advantage over most MMCs and CMCs, all other things being equal.

We observe that all of the composites have relatively low-axial CTEs. This results from the combination of low-fiber-axial CTE, high fiber stiffness, and low matrix stiffness. Note that the axial CTEs of PMCs reinforced with aramid fibers and some carbon fibers are negative. This means that, contrary to the general behavior of most monolithic materials, they contract when heated. The transverse CTEs of the composites are all positive, and much larger than the magnitudes of the corresponding axial CTEs. This results from the high CTE of the matrix and a Poisson effect caused by constraint of the matrix in the axial direction and lack of constraint in the transverse direction. The transverse CTE of aramid composites is particularly high because the fibers have a relatively high positive radial CTE.

The axial thermal conductivities of composites reinforced with glass, aramid, boron, and a number of the carbon fibers are relatively low. In fact, E-glass and aramid PMCs are often used as thermal insulators. As Table 13 shows, most PMCs have relatively high thermal resistivities in the transverse direction, as a result of the low thermal conductivities of the matrix and the fibers in the radial direction. Through-thickness conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites.

Table 14 shows the inplane thermal conductivities and CTEs of quasi-isotropic laminates made from the same material as in Table 13. Here again, a fiber volume fraction of 60% is assumed.

We observe that the CTEs of the quasi-isotropic composites are higher than the axial values of corresponding unidirectional composites. Note, however, that the CTEs of quasi-isotropic composites reinforced with aramid and carbon fibers are very small. By appropriate selection of fiber, matrix, and fiber volume fraction, it is possible to obtain quasi-isotropic materials with CTEs very close to zero. Note that through-thickness CTEs for these laminates typically will be positive and relatively large. However, this is not a significant issue for many applications.

Turning to thermal conductivity, we find that quasi-isotropic laminates reinforced with UHM pitch carbon fibers have an inplane thermal conductivity similar to that of aluminum alloys, while UHK pitch carbon fibers provide laminates with a conductivity more than 50% higher. Both materials have densities 35% lower than aluminum.

As mentioned above, through-thickness thermal conductivities of laminates tend to be similar to the transverse thermal conductivities of unidirectional composites, which are relatively low. However, if laminate thickness is small, this may not be a significant limitation.

### Physical Properties of Metal Matrix Composites

In this section, we consider physical properties of selected unidirectional fiber-reinforced MMCs and of silicon carbide particle-reinforced aluminum MMCs.

| Table 13 Physical Properties of Selected Unidirectional Polymer Matrix Composites |                                      |                                                           |                                                                |                                                              |                                                                   |

***Physical Properties of Continuous Fiber-Reinforced Metal Matrix Composites.*** Table 11 presents physical properties of unidirectional composites consisting of UHK pitch carbon fibers in aluminum and copper matrices. These materials both have very low, slightly negative axial CTEs for the assumed fiber volume fraction of 50%. As the table shows, the axial thermal conductivities for MMCs with aluminum and copper matrices are substantially greater than that of monolithic copper. A major advantage of having thermally conductive matrix materials is that the resulting composite transverse and through-thickness thermal conductivities are more than an order of magnitude higher than those of an epoxy–matrix composite.

Table 12 presents the properties of quasi-isotropic composites composed of aluminum and copper matrices reinforced with UHK pitch carbon fibers. Here, the fiber volume fraction of about 26% has been chosen to achieve an inplane similar to that of aluminum oxide, 6.5 ppm/K (3.6 ppm/°F). The inplane thermal conductivities of the aluminum- and copper-matrix composites are 290 W/m · K (168 BTU/h · ft · °F) and 400 W/m · K (230 BTU/h · ft · °F), respectively. These values are considerably greater than those of any other material with a similar CTE, with the exception of diamond particle-reinforced copper, which is discussed later. Because of the lower fiber volume fractions, the through-thickness thermal conductivities of these composites will be somewhat higher than those of the unidirectional composites presented in Table 11.

***Physical Properties of Particle-Reinforced Metal Matrix Composites.*** In this section, we consider the physical properties of silicon carbide particle-reinforced aluminum and diamond particle-reinforced copper.

***Physical Properties of Silicon Carbide Particle-Reinforced Metal Matrix Composites.*** The physical properties of particle-reinforced composites tend to be isotropic (in three dimensions). As for all composites, the physical properties of silicon carbide particle-reinforced aluminum depend on constituent properties and reinforcement volume fraction. Figure 4 shows how the CTE of (SiC)<sub>p</sub>/Al varies with particle volume fraction for typical commercial materials. Table 15 presents density and CTE for several specific volume fractions, along with data for monolithic aluminum, titanium, and steel.

Thermal conductivity depends strongly on the corresponding properties of the matrix, reinforcement, and particle volume fraction. The thermal conductivity of very pure silicon carbide is slightly higher than that of copper. However, those of commercial particles are much lower. The thermal conductivities of silicon carbide particle-reinforced aluminum used in electronic packaging applications tend to be in the range of monolithic aluminum alloys, about 160–218 W/m · K (92–126 Btu/h · ft · °F).

***Physical Properties of Diamond Particle-Reinforced Copper Metal Matrix Composites.*** Table 12 presents the physical properties of diamond particle-reinforced copper composites, which are developmental materials. As for other particle-reinforced composites, the properties can be expected to be relatively isotropic. This material has a thermal conductivity somewhat higher than that of monolithic copper, a much lower density, and a CTE in the range of semiconductors and ceramic substrates. This unique combination of properties makes this composite an attractive candidate for electronic packaging applications.

Table 15 Physical Properties of Silicon Carbide Particle-Reinforced Aluminum

| Property                                                                    | Aluminum<br>(6061-T6) | Titanium<br>(6Al-4V) | Steel<br>(4340) | Composite Particle Volume Fraction |                  |                  |

| Thermal Conductivity,<br>$W/m \cdot K$ ( $Btu/h \cdot ft \cdot ^{\circ}F$ ) | 218 (126)             | 16 (9.5)             | 17 (9.4)        | 160–220 (92–126)                   | 160–220 (92–126) | 160–220 (92–126) |
| Density, $g/cm^3$ ( $Pci$ )                                                 | 2.77 (0.10)           | 4.43 (0.16)          | 7.76 (0.28)     | 2.88 (0.104)                       | 2.96 (0.107)     | 3.00 (0.108)     |

### Physical Properties of Ceramic Matrix Composites

As discussed in Section 1, there are many CMCs and they are at various stages of development. One of the more mature systems is silicon carbide fiber-reinforced silicon carbide (SiC/SiC). For a fabric-reinforced composite with a fiber volume fraction of 40%, the density is  $2.5 \text{ g/cm}^3$  (0.090 Pci), the CTE is  $3 \text{ ppm/K}$  ( $1.7 \text{ ppm/}^\circ\text{F}$ ), the inplane thermal conductivity is  $19 \text{ W/m} \cdot \text{K}$  ( $11 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ), and the through-thickness value is  $9.5 \text{ W/m} \cdot \text{K}$  ( $5.5 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ).

### Physical Properties of Carbon/Carbon Composites

The CTE of CCCs depends on fiber type, volume fraction, and geometry and matrix characteristics. In the fiber direction, CTE tends to be negative with a small absolute value. Perpendicular to the fiber direction, composite CTE is dominated by matrix properties. As a rule, the magnitude of transverse CTE is small. Both positive and negative values have been reported.

It is well known that in some forms carbon has exceptionally high thermal conductivities. For example, pyrolytic graphite can have a thermal conductivity as high as  $2000 \text{ W/m} \cdot \text{K}$  ( $1160 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ), five times that of copper. The conductivity of some types of diamond is much higher. Some CCCs also have very high thermal conductivities. Values have been reported as high as  $400 \text{ W/m} \cdot \text{K}$  ( $230 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ) for quasi-isotropic composites and  $700 \text{ W/m} \cdot \text{K}$  ( $400 \text{ Btu/h} \cdot \text{ft} \cdot ^\circ\text{F}$ ) for unidirectional materials.

### 1 INTRODUCTION

The world has recently undergone two materials ages, the plastics age and the composite age. In the midst of these two ages a new era has developed. This is the smart materials era. According to early definitions, smart materials are materials that respond to their environments in a timely manner.<sup>1-4</sup>

The definition of smart materials has been expanded to materials that receive, transmit, or process a stimulus and respond by producing a useful effect that may include a signal that the materials are acting upon it. Some of the stimuli that may act upon these materials are strain, stress, temperature, chemicals (including pH stimuli), electric field, magnetic field, hydrostatic pressure, different types of radiation, and other forms of stimuli.<sup>5</sup>

The effect can be caused by an absorption of a proton, of a chemical reaction, of an integration of a series of events, of a translation or rotation of segments

within the molecular structure, of a creation and motion of crystallographic defects or other localized conformations, of an alteration of localized stress and strain fields, and of others. The effects produced can be a color change, a change in index of refraction, a change in the distribution of stresses and strains, or a volume change.<sup>5</sup>

Another important element of a smart material is that the action of receiving stimuli and responding to the stimuli to produce a useful effect is that it must be reversible. Another feature that is an important factor in determining if a material is smart pertains to its asymmetrical nature. This is primarily critical for the piezoelectric materials. Other types of smart materials exhibit this trait. However, little research has been performed to verify this observation.

Also, it should be pointed out that the word *intelligent* is used to describe smart materials. The notation *smart* has been overused as a means to market materials and products.

From the purist point of view materials are smart if at some point within their performance history they act reversible to a stimulus. Materials that formally have the label of being smart include piezoelectric materials, electrostrictive materials, electrorheological materials, magnetorheological materials, thermo-responsive materials, pH-sensitive materials, ultraviolet-(UV) sensitive materials, smart polymers, smart gels (hydrogels), smart catalysts, and shape memory alloys. In this treatment of the subject we will be using some of these classifications and in some cases, the classification of a particular material may appear to be in error. This will be done to illustrate the rapid growth of the field of smart materials and the rediscovery of the smart behavior of materials known for centuries. As we continue to better understand the smartness of materials, our definitions will change. In each material section there will be discussions pertaining to the material definition, types of materials that belong to that class, properties of the members, and applications of the materials. In some cases a more detailed discussion of application will be given to both illustrate the benefit of these materials and to simulate the use of these materials in new applications. This is being done in the spirit of this handbook.

Another important feature of smart materials is their inclusion in structures. These are known as smart structures. Smart structures are simply structures with at least one smart material incorporated within its structure and that from the effect of the smart material cause an action. A smart structure may have sensors (nerves), actuators (muscles), and a control (brain). Thus, you can see the term *biomimetic* associated with smart structures. Smart structures are being designed to make our life more productive and easy. And with the number of sensors, actuators, and control systems available, coupled with the materials and the genius of scientists and engineers, these structures are being more noticeable and numerous. Reading nontechnical magazines, watching television, and going to stores can verify this.

In a silly way the growth of smart structures can be illustrated by an article that appeared on page D11 of the Thursday 14, 2000, issue of the *New York Times*. This article describes the "Big Mouth Billy Bass," the singing fish. The article described the smartness of this novel toy.

Examples of technical applications of smart structures are structures such as composite materials embedded with fiber optics, actuators, sensors, microelec-

tromechanical systems (MEMS), vibration control, sound control, shape control, product health or lifetime monitoring, cure monitoring, intelligent processing, active and passive controls, self-repair (healing), artificial organs, novel indicating devices, designed magnets, damping, aeroelastic stability, and stress distributions. Smart structures are found in automobiles, space systems, fixed- and rotary-wing aircrafts, naval vessels, civil structures, machine tools, recreation, and medical devices.<sup>5,6</sup>

Another feature that is important about smart materials and structures is that they encompass all fields of science and engineering. Thus when searching for information on smart materials and structures, there are numerous sources, web sites, and professional societies that deal with the technology.

## 2 PIEZOELECTRIC MATERIALS

The simplest definition of piezoelectric materials can be obtained by first breaking the word into *piezo* and *electric*. *Piezo* is from the Greek word *piezein* that means to press tightly or squeeze. Combining *piezein* with electric we have “squeeze electricity.” And that to the first estimation is a very good definition.

The history of piezoelectric materials is relatively simple and only the highlights will be presented. In 1880, Pierre and Paul-Jean Curie showed the piezoelectric effect in quartz and Rochelle salt crystals. Their first observations were made by placing weights on the faces of particular crystal cuts, like the X cut quartz plate, detecting charges on the crystal surfaces, and demonstrating that the magnitude of charge was proportional to the applied weight. This phenomenon has become to be known as the direct pressure electric piezoelectric effect. In 1881 G. Lippmann made the prediction that a crystal such as quartz would develop a mechanical strain when an electric field was applied. In the same year the Curies reported the converse pressure electric piezoelectric effect with quartz and Rochelle salt. They showed that if certain crystals were subjected to mechanical strain, they became electrically polarized and the degree of polarization was proportional to the applied strain. The French inventor Langevin developed the first SONAR, using quartz crystals in 1920. During the 1940s researchers discovered and developed the first polycrystalline, piezoelectric ceramic, barium titanate. One of the significant advantages of piezoelectric ceramics over piezoelectric crystals is their ability to be formed in a variety of shapes and sizes. In 1960, researchers discovered a weak piezoelectric effect in whalebone and tendon that lead to intense search for other piezoelectric organic materials. And in 1969, Kawai found very high piezoelectric activity in polarized polyvinylidene fluoride.<sup>7,8</sup>

The piezoelectric effect exists in a number of naturally occurring crystals such as quartz, tourmaline, and sodium potassium tartrate. For a crystal to exhibit the piezoelectric effect, it must not have a center of symmetry. When a stress (tensile or compressive) is applied to a crystal with a center of symmetry, it will alter the spacing between the positive and negative sites in each elementary cell unit, thus causing a net polarization at the crystal surface. The effect is approximately linear. The polarization is directly related to the applied stress. It is directional dependent. Thus, compressive and tensile forces will generate electric fields and voltages of opposite polarity. The effect is also reciprocal; thus when the crystal

is exposed to an electric field, it undergoes an elastic strain changing its length based upon the field polarity.

As previously mentioned, the ceramic-type materials play an important role in the area of piezoelectrics. Piezoelectric ceramics are polycrystalline ferroelectric materials with a perovskite crystal-type structure. The crystal structure is tetragonal/rhombohedral with a close proximity to cubic in nature. Piezoelectric ceramics have the general formula of  $A^{2+}B^{4+}O_3^{2-}$ . The letter A represents a large divalent metal ion such as barium or lead, and B is one or more tetravalent metal ion such as titanium or zirconium or manganese. These ceramics are considered to be masses of minute crystallinities that change crystal forms at the Curie temperature. Above the Curie temperature, the ceramic crystallinities have a simple cubic symmetry. This form is centrosymmetric with positive and negative charge sites coinciding, thus there are no dipoles present. The material is considered to be paraelectric. Below the Curie temperature, the ceramic crystallinities have a tetragonal symmetry; this form lacks a center of symmetry with the positive and negative charge sites that no longer coincide, thus each unit cell now has an electric dipole that may be reversed and switched to certain direction by the application of an electric field. The material is now considered to be ferroelectric.

The piezoelectric properties of the ceramics can be enhanced by applying a large electric field at an elevated temperature, thus generating an internal remnant polarization that continues long after the removal of the electric and thermal fields. This technique is known as poling. The poling of piezoelectric ceramics has eliminated the use of piezoelectric crystals in many applications.

The vinylidene fluoride monomer,  $CH_2=CF_2$ , yields the semicrystalline polymer, polyvinylidene fluoride (PVDF), upon polymerization. This polymer was found to be highly piezoelectric. Polyvinylidene fluoride is manufactured in sheet form from the nonpolar  $\alpha$ -phase film extruded from the melt. The extruded film is uniaxially stretched. This process rotates the long polymer chains and forms the polar beta phase. The beta phase is needed for the high piezoelectricity. The final step consists of reorientation of the randomly directed dipoles associated with the stretched  $\beta$  phase by applying a poling field in the direction normal to the plane of the film. The resulting piezoelectric polyvinylidene fluoride has orthotropic symmetry.

Copolymers and rubber and ceramic blends of polyvinylidene fluoride have been prepared for use as piezoelectric materials. The most common copolymer is one based on the polymerization reaction of vinylidene fluoride and trifluoroethylene. Polyvinylidene fluoride and its copolymers with trifluoroethylene have low mechanical quality factors, high hydrostatic mode responses, and their acoustic impedance is similar to water, thus making them ideal for underwater hydrophone applications.<sup>9</sup>

A series of polyimides has been developed at NASA Langley for use in piezoelectric applications. These polyimides have pendant trifluoromethyl ( $-CF_3$ ) and cyano ( $-CN$ ) polar groups. Whenever these polyimides are exposed to applied voltage of the order of 100 MV/m at elevated temperatures, the polar groups developed a high degree of orientation thus resulting with polymer films with high piezoelectric and pyroelectric properties. The piezoelectric response for these polyimides is in the same vicinity to those of polyvinylidene

fluoride at room temperature. However, the piezoelectric response of the polyimides is greater at elevated temperatures.<sup>10</sup>

Multiphase piezoelectric composites have been developed for their synergetic effect between the piezoelectric activity of monolithic ceramics and the low density of nonpiezoelectric polymeric materials. One class of piezoelectric composites that has been developed is the smart tagged composites. These piezoelectric composites are PZT-5A particles embedded into an unsaturated polyester polymer matrix and are used for structural health monitoring. Conductive metal-filled particles with polyimides films have been explored for microelectronic applications. The use of graphite-filled polyimides has shown potential as micro-sensors and actuators.

Piezoelectric materials have been used in thousands of applications in a wide variety of products in the consumer, industrial, medical, aerospace, and military sectors. When a piezoelectric material is subjected to a mechanical stress an electric charge is generated across the material. The ability of a material to generate a charge or electric field when subjected to a stress is measured by the piezoelectric voltage coefficient (*g*).

The converse effect occurs when a piezoelectric material becomes strained when placed in an electric field. Under constant stress conditions, the general equation for the piezoelectric charge coefficient (*d*) can be expressed as the change in the strain (*S*) of the piezoelectric material as a function of the applied electric field (*E*).

It should be denoted that piezoelectric materials are also pyroelectric. They generate electric charge as they undergo a temperature change. Whenever their temperature is increased, a voltage develops having the same orientation as the polarization voltage. Whenever the temperature is decreased, a voltage develops with an opposite orientation opposite to the polarization voltage.<sup>11</sup>

Tables 1–3 show some of the applications of materials that utilize direct and converse piezoelectric effects and the applications of polyvinylidene fluoride piezoelectric film. Specific applications will be discussed.

One of the uses of piezoelectric ceramics and polymers is their application in ink-on-demand printing. Several commercially available ink jet printers are

| Flow/level: fan monitor, fluidic oscillator, doppler ultrasound, solid-state fluid level, laminar/turbulent layer                                                                       |
| Instrumentation                                                                                                                                                                         |
| Machine health monitor: accelerometer, contact microphone, strain gauging                                                                                                               |
| Weather sensors: rain intensity, hail detection, wind velocity                                                                                                                          |
| Active vibration damping: strain gauge array, actuator array                                                                                                                            |
| Nondestructive testing: acoustic emission                                                                                                                                               |
| Ranging: distance, safety                                                                                                                                                               |
| Adaptive optics: fiber optic shutter, deformable mirror, laser scanner                                                                                                                  |
| Oil exploration: hydrophone, seismic geophone                                                                                                                                           |

based upon this technology.<sup>12,13</sup> In this application the impulse ink jet is produced using a cylindrical transducer that is tightly bound to the outer surface of a cylindrical glass nozzle with an orifice ranging from mils to microns in diameter. In addition to this application several industrious researchers have expanded upon this technique by using a printer as a chemical delivery system for the application of doped polymers for organic light-emitting displays. A group of researchers from Princeton University has used a color ink jet printer based upon piezoelectric technology with a resolution of 640 dots per line and simply replaced the inks with polymer solutions.<sup>14</sup> This technique has also been applied to the manufacture of color filters for liquid-crystal displays.

Another application of the use of piezoelectric polymer film involves the work of a group of researchers at the Thiokol Company and an earlier work<sup>15,16</sup> to monitor adhesive joints. The study showed that during the bonding process, the polyvinylidene fluoride piezoelectric film sensors monitored the adhesive cure ultrasonically and qualitatively determined the presence of significant void content. The study also indicated that normal bond stresses were quantified during cyclic loading of single lap joints and electrometric butt joints. The researchers revealed that this was a significant step toward service life predictions. But, more and better-understood monitoring techniques are needed.

An interested application of piezoelectric ceramics can be illustrated in the hundred of vertical pinball machines popular in the Pachinko parlors of Japan. The machines are assembled with stacks of piezoelectric disks that can act as both sensors and actuators. When a ball falls on the stack, the force of impact generates a piezoelectric voltage pulse that in turns generates a response from the actuator stack through a feedback control system. The stack expands, thus throwing the ball out of the hole and moving up a spiral ramp through a sequence of events, and finally repeating the sequence.<sup>17</sup>

### 3 ELECTROSTRICTIVE MATERIALS

Piezoelectric materials are materials that exhibit a linear relationship between electric and mechanical variables. Piezoelectricity is a third-rank tensor. Electrostrictive materials also show a relationship between these two variables. However, in this case, it is a quadratic relationship between mechanical stress and the square of electrical polarization. Electrostriction can occur in any material and is a small effect. One difference between piezoelectric and electrostrictive materials is the ability of the electrostrictive materials to show a larger effect in the vicinity of its Curie temperature. Electrostriction is a fourth-rank tensor property observed both in centric and acentric insulators. This is especially true for ferroelectric materials such as the members of the perovskite family. Ferroelectrics are ferroic solids whose domain walls have the capability of moving by external forces or fields. In addition to ferroelectrics the other principal examples of ferroic solids are ferromagnetics and ferroelastics, both of which have potential as smart materials. Other examples of electrostrictive materials include lead manganese niobate: lead titanate (PMN: PT) and lead lanthanum zirconate titanate (PLZT).

An interesting application of electrostrictive materials is in active optical applications. During the Cold War, the satellites that flew over the Soviet Union used active optic systems to eliminate the atmospheric turbulence effects. Elec-

trostrictive materials have the advantage over piezoelectric materials in adjusting the position of optical components due to the less amount of hysteresis associated with the motion. Work on active optic systems has continued. Similar multilayer actuators were used to correct the position of the optical elements in the Hubble telescope. Supermarket scanners use actuators and flexible mirrors to read bar codes optically.<sup>17</sup>

Other examples of this family may be included in the electroactive polymers. This name has appeared in the technical literature for approximately a decade with an increasing interest in the last couple of years. Electroactive polymers include any polymer that is simulated by electricity and responds to its effect in a reversible manner. This classification is sort of a melting pot of smart materials.<sup>18</sup>

#### 4 MAGNETOSTRICTIVE MATERIALS

Magnetorestrictive materials have the material response of mechanical deformation when stimulated by a magnetic field. Shape changes are the largest in ferromagnetic and ferrimagnetic materials. The repositioning of domain walls that occur when these solids are placed in a magnetic field leads to hysteresis between magnetization and an applied magnetic field. When a ferromagnetic material is heated above its Curie temperature, these effects disappear. The microscopic properties of a ferromagnetic solid are different than a ferrimagnetic solid. The magnetic dipoles of a ferromagnetic solid are aligned parallel. The alignment of dipoles in a ferrimagnetic solid can be either parallel or in other directions.<sup>5,19,20</sup>

Magnetorestrictive materials are usually inorganic in chemical composition and alloys of iron, nickel, and doped with rare earths. The most effective magnetorestrictive material is another alloy developed at the Naval Ordnance Laboratory, TERFENOL-D. It is an alloy of terbium, dysprosium, and iron with a formula of  $Tb_xDy_{1-x}Fe$  with  $x$  between 0.27 and 0.30 and  $y$  between 1.90 and 1.98. The full effect of magnetorestriction occurs in crystalline materials. One of the hindrances preventing magnetorestrictive materials reaching commercial significance has been cost. Over the past three decades there has been a great deal of development of giant magnetorestrictive materials, colossal magnetorestrictive materials, and organic and organometallic magnets.<sup>5,21</sup>

The giant magnetorestrictive effect was first observed in iron-chromium laminates in 1988. These laminates consisted of alternating layers of 50-Å-thick iron with chromium layers of various thicknesses. The iron layers oriented themselves with antiparallel magnetic moments. A magnetic field of 20 kOe applied in the plane of the iron layers will uncouple this antiferromagnetic orientation. Since the magnetic orientation of one layer is controlled, another layer is free to rotate with an applied field; this change in orientation of the two layers produces a magnetorestrictive effect. This discovery of giant magnetorestrictive materials enhanced the increased sensitivities in the hard disk drive heads at a cost-effective price.

In the 1990s, researchers further enhanced the field of magnetorestrictive materials with the development of colossal magnetorestrictive materials. Ratios of magnetorestrictive effect in excess of 100,000% were observed. These new materials were found to be epitaxial lanthanum–calcium–manganese–oxygen thin

films, polycrystalline lanthanum–yttrium–calcium–manganese–oxygen and polycrystalline lanthanum–barium–manganese–oxygen. These again enhanced the product performance at costs less than the original magnetorestrictive materials.<sup>21</sup>

Magnets that exhibit commercial potential should have magnetic saturation and coercive field properties that are operational at low temperatures. Magnets are useful below their critical temperature. Most inorganic magnets have critical temperatures well above room temperature.

The first organometallic magnet was the ionic salt complex of ferric bis(pentamethylcyclopentadienide) and tetracyanoethylene. This complex was a ferromagnet below its critical temperature of 4.8 K. The highest effective critical temperature of an organometallic magnet was in the vicinity of 400 K.<sup>22</sup>

Organic magnets are different than organometallic magnets for two reasons. The first is obvious. Organic-based magnets do not contain metal atoms. This causes a great deal of rethinking the principles of magnetism. The second difference refers to the fact the coupled spins of the organic magnets reside only in the *p* orbitals while the coupled spins of the organometallic magnets can reside in either the *p* orbitals or the *d* orbitals or a combination of the two. A series of organic magnets based upon the nitroxide chemistry was synthesized and their magnetic behavior studied between 0.6 and 1.48 K. The most studied compound of these nitroxide-based magnets was 4-nitrophenylnitronyl nitroxide. This compound showed a saturation magnetization equivalent to one spin per molecule. This is indicative of ferromagnetic behavior.<sup>5,22</sup>

## 5 ELASTORESTRICTIVE MATERIALS

This class of smart materials is the mechanical equivalent to electrorestrictive and magnetorestrictive smart materials. These smart materials exhibit high hysteresis between stress and strain. The motion of ferroelastic domain walls causes the hysteresis. This motion of the ferroelastic domain walls is very complicated and complex near a martensitic phase transformation. At this phase change, two types of crystal structural changes occur. One is induced by mechanical stress and the other is by domain wall motion. Martensitic shape memory alloys have wide, diffuse phase changes and the ability to exist in both high- and low-temperature phases. The domain wall movements disappear with total change to the high-temperature phase.<sup>5,19,20</sup> The elastorestrictive smart material family is in its infancy.

## 6 ELECTORRHEOLOGICAL MATERIALS

The rheological materials are an exciting group of smart materials. Electrorheological and magnetorheological materials can change their rheological properties instantly through the application of either an electric or magnetic field. The electrorheological materials (fluids) have been known for several centuries. The rheological or viscous properties of these fluids, which are usually uniform dispersions, or suspensions of particles within a fluid are changed with the application of an electric field. The mechanism of how these electrorheological fluids work is simple. In an applied electric field the particles orient themselves in fiberlike structures (fibrils). When the electric field is off, the fibrils disorient themselves. Another way to imagine this behavior is to consider logs in a river.

If the logs are aligned, they flow down the river. If they are disordered, they will cause a log jam thus clogging up the river. A typical example of an electrorheological fluid is a mixture of corn starch in silicone oil. Another fluid that has been experimented with as a replacement for the silicone oil has been chocolate syrup. Another feature of electrorheological systems is that their damping characteristics can be changed from flexible to rigid and vice versa. Electrorheological fluids were evaluated using a single-link flexible-beam test bed. The beam was a sandwich configuration with electrorheological fluids distributed along its length. When the beam was rapidly moved back and forth, the electrorheological fluid was used to provide flexibility during the transient response period of the maneuver for speed and made rigid at the end point of the maneuver for stability. A practical way of viewing this behavior is to compare it with fly fishing.<sup>5</sup> It has been suggested to use rheological fluids in the construction of fishing rods and golf clubs.

## 7 MAGNETORHEOLOGICAL MATERIALS

The magnetorheological materials (fluids) are the magnetic equivalent of electrorheological fluids. These fluids consist of either ferromagnetic or ferrimagnetic particles that are either dispersed or suspended within; and the applied stimulus is a magnetic field. A simple magnetorheological fluid consists of iron powder in motor oil. The Lord Corporation provided a clever demonstration of magnetorheological fluids. They supplied an interlocking two-plastic-syringe system filled with a magnetorheological fluid and two small magnets. The fluid flows freely, without the magnets placed in the middle of the two syringes. With the two magnets in place, the fluid flow completely stops.

An interesting adaptation of magnetorestrictive fluids is a series of elastomeric matrix composites embedded with iron particles. During the thermal cure of the elastomer, a strong magnetic field was applied to align the iron particles into chains. These chains of iron particles were locked into place within the composite through the cross-linked network of the cured elastomer. If a compressive force stimulated the composite, it was 60% more resistant to deformation in a magnetic field. If the composite was subjected to a shear force, its magnetic field induced modulus was an order of magnitude higher than its modulus in a zero magnetic field.<sup>5,23</sup>

A recent well-thought article described attempts to enhance the properties of epoxies with magnetic fields. The study did show the low conversion rates of the epoxy with the hardener; economically generated magnetic fields had an effect on the properties of the final composite. At the high conversion of the reactants there exists a need to drive the scarce unreacted glycidyl and amine functionalities together. And only the magnetic fields generated by superconducting electromagnets are capable of this.<sup>24</sup>

There continues to be a great deal of research into magnets and magnetism. A new area of research involves magnetic nanocomposite films. Magnetic particles exhibit size effects. Below a critical size, magnetic clusters comprise single domains, whereas with bulk materials there are multiple domains. Nanomagnets show unusual properties such as superparamagnetism and quantum tunneling of magnetization. These unique properties of magnetic nanoclusters can lead to applications in information storage, color imaging, magnetic refrigeration, fer-

rofluids, cell storing, medical diagnosis, and controlled drug delivery. A nanocomposite is considered to be the incorporation of these nanoclusters into polymeric matrices such as polyaniline.<sup>25</sup>

## 8 THERMORESPONSIVE MATERIALS

Amorphous and semicrystalline thermoplastic polymeric materials are unique due to the presence of a glass transition temperature. At their glass transition temperatures, the specific volume of polymer and its rate of change changes. This transition affects a multitude of physical properties. Numerous types of indicating devices could be developed based upon the stimuli-response (temperature-specific volume) behavior. This chapter contains several examples of this type of behavior; however, its total impact is beyond the scope of this chapter. To take advantage of this behavior in product development or material selection it requires reviewing the necessary requirements in the many polymer references.

A few examples that illustrate thermoresponsive behavior that are a little unique are being included in this chapter. One refers to the polyethylene/poly(ethylene glycol) copolymers that were used to functionalize the surfaces of polyethylene films.<sup>5,26</sup> One may refer to this illustration as being a “smart surface” or functionally gradient surfaces. When the film is immersed in an aqueous dispersion of the copolymer, the ethylene glycol moieties attach to the polymer film surface resulting in a film surface having solvation behavior similar to poly(ethylene glycol) itself. Due to the inverse temperature-dependent solubility behavior of poly(alkene oxide)s in water surface modified polymers are produced that reversibly change their hydrophilicity and solvation with changes in temperatures.<sup>27</sup> Similar behaviors have been observed as a function of changes in pH.<sup>28–31</sup>

Another interesting example of materials that respond smartly to changes in temperature are the fabrics based upon poly(ethylene glycol)-modified cottons, -modified polyesters, and -modified polyamide/polyurethanes. A combination of the thermoresponsiveness of these fabrics with a sensitivity to moisture resulted in a family of fabrics that can serve as smart pressure bandages. When exposed to an aqueous medium such as blood, these fabrics contract and apply pressure. Once the fabric dries, it releases the pressure.<sup>23</sup>

Polymers based upon the monomer vinyl methyl ether have the unique behavior of shrinking upon heating to approximately 40°C. In the right design with normal behaving polymers, one can construct a device that can grasp objects like a hand.

## 9 pH-SENSITIVE MATERIALS

By far the widely known chemical classes of pH-sensitive materials are the acids, bases, and indicators. The indicators fit the definition of smart materials by changing colors, as a function of pH and the action is reversible.

Other examples of pH-sensitive materials include some of the smart gels and smart polymers mentioned in this chapter. There are a large number of pH-sensitive polymers and gels that are used in biotechnology and medicine. Usually these materials are prepared from various combinations of such monomers and polymers such as methacrylic acid, methyl methacrylate, carboxymethylcellulose, cellulose acetate, cellulose phthalate, hydroxypropylmethylcellulose

phthalate, hydroxypropylmethylcellulose acetate, hydroxypropylmethylcellulose succinate, diethylaminoethyl methacrylate, and butyl methacrylate.<sup>32</sup>

## 10 LIGHT-SENSITIVE MATERIALS

There are several different material families that exhibit different types of behavior to a light stimulus. Electrochromism is a change in color as a function of an electrical field. Other types of behavior for light-sensitive materials are thermochromism, color change with heat, photochromism, color change with light, and photostrictism, shape changes caused by changes in electronic configuration due to light.<sup>5,19,20</sup>

Electrochromic smart windows have been intensively researched over the past few decades. There have been over 1800 patents issued for optical switching devices with the bulk of these being issued in Japan. A typical switchable glass is multilayered with an electrochromic device embedded inside. A window device may have glass with an interior conductive oxide layer both on the top and bottom. Inside of the sandwich of glass and conductive oxide is the electrochromic device. This device consists of an electrochromic layer, an ion storage layer, and between these two layers, an ion conductor.

An interesting light-sensitive material with both electro- and thermochromism behaviors,  $\text{Li}_x\text{VO}_2$ , was evaluated for a smart window application.<sup>33</sup>

Materials have been developed to exhibit both photochromic and photographic (irreversible behavior to light) behaviors. One such system is based upon a substituted indolinospirobenzopyran embedded in a polystyrene matrix. This system performs as a photochromic system at low exposure in the ultraviolet range and as a photographic system at high exposures. The image can be devisualized by heat and can be restored with UV irradiation many times.<sup>34</sup>

## 11 SMART POLYMERS

The term *smart polymers* was almost dropped as a classification for smart materials in this treatment of the subject. It is very confusing. Each field of science and engineering has its own definition for a smart polymer and each can fit in another classification, and its distinction in smartness can be confusing at times. It is being included as a separate class due to several excellent articles written with smart polymers in the title.

In medicine and biotechnology, smart polymer systems usually pertain to aqueous polymer solutions, interfaces, and hydrogels. Smart gels or hydrogels will be treated separately. Smart polymers refer to polymeric systems that are capable of responding strongly to slight changes in the external medium: a first-order transition, accompanied by a sharp decrease in the specific volume of the polymer. If the external medium is temperature, this transition is known as the glass transition temperature of the polymer and several properties of the polymer changes. These properties include volume, coefficient of thermal expansion, specific heat, heat conductivity, modulus, and permeation. Manipulating the detection around the glass transition temperature of the polymer can develop smart devices. There are numerous examples in product development that have resulted in failure because of not taking into account the glass transition temperature of the polymer. And it should be noted, as the polymer cools down from high

temperatures and goes below its glass transition temperature, its below glass transition properties are returned and vice versa.

Smart polymers can respond to stimuli such as temperature, pH, chemical species, light, UV radiation, recognition, electric fields, magnetic fields, and other types of stimuli. The resulting response can be changes in phases, shape, optics, mechanical strengths, electrical and thermal properties, reaction rates, and permeation rates.

## 12 SMART (INTELLIGENT) GELS (HYDROGELS)

In the literature you can find these smart materials under a variety of names as reflected by the title of this section. The concept of smart gels is a combination of the simple concept of solvent-swollen polymer networks in conjunction with the material being able to response to other types of stimuli. A partial list of these stimuli includes temperature, pH, chemicals, concentrations of solvents, ionic strengths, pressure, stress, light intensity, electric fields, magnetic fields, and different types of radiation.<sup>35–39</sup> The founding father of these smart gels, Toyochi Tanaka, first observed this phenomenon in swollen clear polyacrylamide gels. Upon cooling, these gels would cloud up and become opaque. Upon warming, these gels regained their clarity. Upon further investigation to explain this behavior, it was found that some gel systems could expand to hundreds of times their original volume or could collapse to expel up to 90% of their fluid content with a stimulus of only a 1°C change in temperature. Similar behavior was observed with a change of 0.1 pH units.

These types of behaviors lead to the development of gel-based actuators, valves, sensors, controlled-release systems for drugs and other substances, artificial muscles for robotic devices, chemical memories, optical shutters, molecular separation systems, and toys. Other potential systems for the development of products with smart (intelligent) gels (hydrogels) include paints, adhesives, recyclable absorbents, bioreactors, bioassay systems, and display.

There are numerous examples of the commercialization of these smart gels in one of the cited reference.<sup>35</sup> This chapter will only include a few examples of smart gels. One such smart gel consists of an entangled network of two polymers, a poly(acrylic acid) (PAA) and a triblock copolymer of poly(propylene oxide) (PPO) and poly(ethylene oxide) (PEO) with a sequence of PEO–PPO–PEO. The PAA portion is a bioadhesive and is pH responsive, the PPO moieties are hydrophobic that assist solubilize lipophilic substances in medical applications, and the PEO functionalities tend to aggregate thus resulting in gelation at body temperatures. Another smart gel system with a fairly complex composition consists of citosan, a hydrolyzed derivative of chitin (a polymer of *N*-acetylglucosamine that is found in shrimp and crab shells), a copolymer of poly(*N*-isopropylacrylamide) and poly(acrylic acid), and a graft copolymer of poly(methacrylic acid) and poly(ethylene glycol). This gel system was developed for the controlled release of insulin in diabetics. Polyampholytic smart hydrogels swell to their maximum extent at neutral pH values. When such gels, copolymers of methacrylic acid 2-(*N,N*-dimethylamino)ethyl methacrylate, are subjected to either acidic or basic media, they undergo rapid dehydration.<sup>39</sup>

One very unusual smart gel is based upon the polymerization of *N*-isopropylacrylamide, a derivative of tris(2,2'-bipyridyl)ruthenium(II) that has a

polymerizable vinyl group, and *N,N'*-methylenebisacrylamide. It is a self-oscillating gel that simulates the beating of the heart with color changes.<sup>40</sup>

### 13 SMART CATALYSTS

The development of smart catalysts is a new field of investigation and has shown a great deal of activity in the universities of the oil-producing states. One such smart catalyst is rhodium-based with a poly (ethylene oxide) backbone. Smart catalysts such as this one function opposite as a traditional catalyst, that is, as the temperature increases, it becomes less soluble, precipitating out of the reaction solution, thus becoming inactive. As the reaction solution cools down, the smart catalyst redissolves and thus becomes active again.<sup>5,23</sup> Other smart catalyst systems are being developed that dissociate at high temperatures (less active) and recombine at low temperatures (more active).<sup>5,27</sup>

### 14 SHAPE MEMORY ALLOYS

The shape memory effect in metals is a very interesting phenomenon. Just imagine taking a piece of metal and deforming it completely and then restoring it to its original shape with the application of heat. Taking a shape memory alloy spring and hanging a weight on one end of the spring can easily illustrate this. After the spring has been stretched, heat the spring with a hot air gun and watch it return to its original length with the weight still attached.

These materials undergo a thermomechanical change as they pass from one phase to another. The crystalline structure of such materials as nickel-titanium alloys enters into the martensitic phase as the alloy is cooled below a critical temperature. In this stage the material is easily manipulated through large strains with a little change in stress. As the temperature of the material is increased above the critical temperature, it transforms into the austenitic phase. In this phase the material regains its high strength and high modulus and it behaves normally. The material shrinks during the change from the martensitic to the austenitic phase.<sup>5,19,20</sup>

The nickel-titanium alloys have been the most used shape memory material. This family of nickel-titanium alloys is known as Nitinol (*Nickel Titanium Naval Ordinance Laboratory*), named in part for the laboratory where this material was first observed. Nitinol has been used in military, medical, safety, and robotics applications. Specific applications include hydraulic lines used on F-14 fighter planes, medical tweezers and sutures, anchors for attaching tendons to bones, stents for cardiac arteries, eyeglass frames, and antiscalding valves used in water faucets and showers.<sup>5,41,42</sup>

In addition to the family of nickel-titanium alloys there are other alloys that exhibit the shape memory effect. These alloys are silver-cadmium, gold-cadmium, copper-aluminum-nickel, copper-tin, copper-zinc, combinations of copper-zinc with silicon or tin or aluminum, indium-thallium, nickel-aluminum, iron-platinum, manganese-copper, and iron-manganese-silicon.<sup>43</sup> Not all combinations of either the two or three elements yields an alloy with the shape memory effect thus it is recommended to review the original literature.

In the open literature there are several articles from Mitsubishi Heavy Industries, Ltd. describing the room temperature functional shape memory polyurethanes. To this writer, these studies only attest to the behavior of a polymer at its glass transition temperature. Thus if you wish to describe a polymer's be-

havior at its glass transition temperature and since that free volume change is reversible, you may call it a smart polymer or a shape memory material or a thermoresponsive material. The unique characteristic of these polyurethanes is that their transition occurs in the vicinity of room temperature.<sup>44,45</sup>

## 15 UNUSUAL BEHAVIORS OF MATERIALS

As one researches the field of smart materials and structures, one realizes that there are many smart materials or that there are many material behaviors that are reversible within their lifetime. The ability to develop useful products from smart materials is left up to one's imagination. For example, water is a very unique material. It expands upon freezing. And as we know, the force generated by this expansion causes sidewalks and highways to crack. Now, what if you surround water pipes with a heating system that consists of a heater and water enclosed in piezoelectric polymer or elastomer container that is in a fixed space. As the temperature drops to the freezing point of water, it expands and generates force against the piezoelectric container which in turn generates electricity, thus powering the heater keeping the pipes from freezing.

As previously mentioned, sometimes it is difficult to classify the material and its behavior. One such case involves an assigned patent to the University of Illinois. The title of the patent is "Magnetic gels which change volume in response to voltage changes for magnetic resonance imaging."<sup>46</sup> The patent teaches the use of a matrix that has a magnetic and preferably superparamagnetic component and the capability of changing its volume in an electric field.

Fullerenes are spherically caged molecules with carbon atoms at the corner of a polyhedral structure consisting of pentagons and hexagons. The most stable of the fullerenes is a C<sub>60</sub> structure known as buckyball or buckminsterfullerene. The fullerenes have been under commercial development for the past decade. One application of the fullerenes as a smart material consists of embedding the fullerenes into sol-gel matrices for the purpose of enhancing optical limiting properties.<sup>47</sup>

A semiconducting material with a magnetic ordering at 16.1 K was produced from the reaction of buckyball with tetra(dimethylamino)ethylene. This organic-based magnet had neither the coercivity nor saturation magnetization to function totally as a ferromagnet. The replacement of buckyball with higher carbon number fullerenes in the reaction with tetra(diamethylamino)ethylene did not produce any complexes that showed magnetic ordering.<sup>22</sup>

## 16 COMMENTS, CONCERNS, AND CONCLUSIONS

In dealing with smart materials and structures, there is still a lot of confusion as to the name of these materials and what makes a material or structure smart. There are numerous products with *Smart* in the name that do not meet the definition of being smart, that is, responding to its environment in a reversible manner. The scientist/engineer should not fault the advertising professional for doing his or her job whenever they use the term in a product description. But I must admit I chuckle to myself whenever I see the magazine *Smart Money*. Does this mean that after I spent money it will return to me because it is reversible?

The confusion also exists in the smart materials community with the term *smart polymers*. The applications of most smart polymers center around the polymer's glass transition temperature. As more design engineers became more

familiar with that term and its significance to a design, the term *smart polymer* in some applications will be eliminated and replaced with terms like *working smartly with a polymer*.

We have not addressed the versatility of these smart materials. One such example may involve the smart shock absorbers. Two literature sources discuss the current research that is being focused on vibration suppression in automobiles using smart shock absorbers.<sup>48,49</sup> These smart shock absorbers were developed by Toyota and consisted of multilayer piezoelectric ceramics. These multilayer stacks are positioned near each wheel. After analyzing the vibration signals, a voltage is fed back to the actuator stack that responds by pushing on the hydraulic system to enlarge the motion. Signal processors analyzed the acceleration signals from road bumps and responded with a motion that canceled the vibration.<sup>3,17</sup> Such active piezoelectric systems are used to minimize excess vibrations in helicopter blades and in the twin tails of F-18 fighter jets. One Internet source discussed the work at the University of Rochester with smart shock absorbers using electrorheological fluids. The electrorheological fluids would sense the force of a bump and immediately send an electric signal to precisely alter the amount to dampen the force of the bump thus providing a smoother ride. In an engine mount, electrorheological fluids damp out the vibrations of the engine thus reducing wear and tear on the vehicle. Another application of electrorheological fluids is in the clutches to reduce the wear between the plates as a driver shifts gears. This can reduce the maintenance costs of high-duty trucks.<sup>47</sup> Or one can dampen the vibrations of the road, engine mounts, and other sources on an automobile or heavy-duty truck with magnetorheological fluids. The Lord Corporation has developed a series of trademarked fluids and systems known as Rheonetic that are commercially available for vibration control as well as for noise suppression.<sup>49</sup>

## 17 FUTURE

The future of smart materials and structures is wide open. The use of smart materials in a product and the type of smart structures that one can design is only limited to one's talents, capabilities, and ability to "think out of the box."

In an early work<sup>5</sup> and as part of the short courses taught there were discussions pertaining to future considerations. A lot of the brainstorming that resulted from these efforts is now being explored. And there are some that were in the conceptual stage are moving forward. Look at the advances made with the automobile and what information and comforts it provides through smart materials and structures.

We can take automobiles to a garage for service and it is hooked up to a diagnostic computer and the mechanic is told what is wrong with the car. Or we have a light on the dashboard that signals "maintenance required." Would it not be better for the light to inform us as to the exact nature of the problem and the severity of it? This approach mimics a cartoon that appeared several years ago of an air mechanic near a plane in a hanger. The plane says "Ouch" and the mechanic says "Where do you hurt?"

One application of smart materials and their application is the earlier work mentioned of using a piezoelectric ink jet printer to serve as a chemical delivery to print organic light-emitting polymers in a fine detail on various medium. Why not take the same application to synthesize smaller molecules? With the right

set one could synthesize smaller molecules in significant amounts for characterization and evaluation and in such a way that we could perform design of experiments with relative ease.

A topic of research that was in the literature a few years ago was “smart clothes” or “wearable computers” being studied at MIT. The potential of this concept is enormous. This sounds wonderful as long as we learn how to work smarter not longer.

### 1 INTRODUCTION

Engineering ceramics possess unique combinations of physical, chemical, electrical, optical, and mechanical properties. Utilizing the gains in basic materials science understanding and advances in processing technology accrued over the past half century, it is now frequently possible to custom tailor the chemistry, phase content, and microstructure to optimize, applications-specific combinations of properties in ceramics (which includes glasses, single crystals, and coatings technologies, in addition to bulk polycrystalline materials). This capability in turn has led to many important, new applications of these materials over the past few decades. Indeed, in many of these applications the new ceramics and glasses are the key enabling technology.

Ceramics include materials that have the highest melting points, highest elastic moduli, highest hardness, highest particulate erosion resistance, highest thermal conductivity, highest optical transparency, lowest thermal expansion, and lowest chemical reactivity known. Counterbalancing these beneficial factors are brittle behavior and vulnerability to thermal shock and impact. Over the past three decades major progress has been made in learning how to design to mitigate the brittleness and other undesirable behaviors associated with ceramics

and glasses. Consequently, many exciting new applications for these materials have emerged over the past several decades.

Among the major commercial applications for these materials are:

- Passive electronics (capacitors and substrates)
- Optonics/photonics (optical fibers)
- Piezoceramics (transducers)
- Mechanical (bearings, cutting tools)
- Biomaterials (hard tissue replacement)
- Refractories (furnace linings, space vehicle thermal protection)
- Electrochemical (sensors, fuel cells)
- Transparencies (visible, radar)

This chapter will provide a brief overview of how ceramics are processed and the ramifications of processing on properties. Next a short discussion of the special issues that one encounters in mechanical design with brittle materials is provided. Short reviews of several of the above engineering applications of ceramics and glasses, which discuss some of the specific combinations of properties that have led design engineers to the selected material(s), follow. A section on how to obtain information on materials sources and information is provided. Tables listing typical properties of candidate materials for each set of applications are included throughout. Finally, some areas of future potential will be discussed.

## 2 PROCESSING OF ADVANCED CERAMICS

The production of utilitarian ceramic artifacts via the particulate processing route outlined in Fig. 1 actually commenced about 10,000 years ago.<sup>1</sup> Similarly, glass melting technology goes back about 3500 years, and as early as 2000 years ago optical glass was being produced.<sup>1</sup> While many of the basic unit processes for making glasses and ceramics are still recognizable across the millennia, the level of sophistication in equipment, process control, and raw material control have advanced by “lightyears.” In addition, the past 50 years has created a fundamental understanding of the materials science principles that underlie the processing–microstructure–property relationships. Additionally, new materials have been synthesized that possess extraordinary levels of performance for specific applications. These advances have led to the use of advanced ceramics and glasses in roles that were unimaginable 50 or 60 years ago. For example, early Egyptian glass ca. 2000 BC had an optical loss of  $\sim 10^7$  dB/km, compared to an optical loss of  $\sim 10^{-1}$  in mid-1980s glass optical fibers,<sup>2</sup> a level of performance that has facilitated the fiber-optic revolution in telecommunications. Similarly, the invention of barium titanate and lead zirconate titanate ceramics, which have much higher piezoelectric moduli and coupling coefficients than do naturally occurring materials, has enabled the existence of modern sonar and medical ultrasound imaging.<sup>3</sup>

The processing of modern ceramics via the particulate route, shown in Fig. 1, is the way that  $\sim 99\%$  of all polycrystalline ceramics are manufactured. Other techniques for producing polycrystalline ceramics, such as chemical vapor dep-

**Fig. 1** Processing of polycrystalline ceramics via the particulate route.

osition<sup>4</sup> or reaction forming<sup>5</sup> are of growing importance but still represent a very small fraction of the ceramic industry. There are three basic sets of unit processes in the particulate route (and each of these three sets of processes may incorporate dozens of subprocesses). The first set of processes involve powder synthesis and treatment. The second set of processes involve the consolidation of the treated powders into a shaped perform, known as a “green” body. The green body typically contains about 50 vol % porosity and is extremely weak. The last set of unit processes utilize heat, or heat and pressure combined, to bond the individual powder particles, remove the free space and porosity in the compact via diffusion, and create a fully dense, well-bonded ceramic with the desired microstructure.<sup>6</sup> If only heat is used, this process is called sintering. If pressure is also applied, the process is then referred to as hot pressing (unidirectional pressure) or hot isostatic pressing [(HIP), which applies uniform omnidirectional pressure].

Each of the above steps can introduce processing flaws that can diminish the intrinsic properties of the material. For example, chemical impurities introduced during the powder synthesis and treatment steps may adversely effect the optical, magnetic, dielectric, or thermal properties of the material. Alternatively, the impurities may segregate in the grain boundary of the sintered ceramic and negatively effect its melting point, high temperature strength, dielectric properties, or optical properties. In green-body formation, platy or high aspect ratio powders may align with a preferred orientation, leading to anisotropic properties. Similarly, hot pressing may impose anisotropic properties on a material. Since ceramics are not ductile materials, they can (usually) not be thermomechanically modified after primary fabrication. Thus, the specific path by which a ceramic component is fabricated can profoundly effect its properties. The properties encountered in a complex shaped ceramic part are often quite different than those

encountered in a simply shaped billet of material. This is an important point of which a design engineer specifying a ceramic component needs to be constantly mindful.

### 3 BRITTLENESS AND BRITTLE MATERIALS DESIGN

Even when ceramics are selected for other than mechanical applications, in most cases some level of strength and structural integrity are required. It is therefore necessary to briefly discuss the issue of brittleness and how one designs with brittle materials before proceeding to discuss applications and the various ceramic and glass materials families and their properties.

The main issues in designing with a brittle material are that a very large scatter in strength (under tensile stress), a lack of capacity for mitigating stress concentrations via plastic flow, and relatively low energy absorption prior to failure dominate the mechanical behavior. Each of these issues is a result of the presence of one or more flaw distribution within or at the surface of the ceramic material and/or the general lack of plastic flow available in ceramics. As a consequence, ceramic and glass components that are subjected to tensile stresses are not designed using a single valued strength (*deterministic design*) as commonly done with metals. Rather, ceramic components are designed to a specified probability of failure (*probabilistic design*) that is set at acceptably low values. The statistics of failure of brittle materials whose strength is determined by a population of varying sized flaws is similar to modeling the statistics of a chain failing via its weakest link. The statistics utilized are known as Weibull statistics. A Weibull probability of failure distribution is characterized by two parameters, the characteristic stress and the Weibull modulus.<sup>7</sup> Computer programs for incorporating Weibull statistical distributions into finite-element design codes have been developed that facilitate the design of ceramic components optimized for low probabilities of failure.<sup>8</sup> The effectiveness of such probabilistic design methodology has been demonstrated by the reliable performance of ceramics in many highly stressed structural applications, such as bearings, cutting tools, turbo-charger rotors, missile guidance domes, and hip prosthesis.

Flaws (strength-limiting features) can be intrinsic or extrinsic to the material and processing route by which a test specimen or a component is made. Intrinsic strength-limiting flaws are generally a consequence of the processing route and may include features such as pores, aggregations of pores, large grains, agglomerates, and shrinkage cracks. While best processing practices will eliminate or reduce the size and frequency of many of these flaws, it is inevitable that some will still persist. Extrinsic flaws can arise from unintended foreign material entering the process stream, i.e., small pieces of debris from the grinding media or damage (cracks) introduced in machining a part to final dimensions. Exposure to a service environment may bring new flaw populations into existence, i.e., oxidation pits on the surface of nonoxide ceramics exposed to high temperatures or may cause existing flaws to grow larger as in the case of static fatigue of glass. In general, one can have several flaw populations present in a component at any time, and the characteristics of each population may change with time. As a consequence of these constantly changing flaw populations, at the present time the state of the art in life prediction of ceramic components for use in extreme environments significantly lags the state of the art in component design.

As in most fields of engineering, there are some rules of thumb that one can apply to ceramic design.<sup>9</sup> While these are not substitutes for a carefully executed probabilistic finite-element design analysis, they are very useful in spotting pitfalls and problems when a full-fledged design cannot be executed due to financial or time constraints.

#### *Rules of Thumb for Design with Brittle Materials*

1. Point loads should be avoided to minimize stress where loads are transferred. It is best to use areal loading (spherical surfaces are particularly good); line loading is next best.
2. Structural compliance should be maintained by using compliant layers, springs or radiusing of mating parts (to avoid lockup).
3. Stress concentrators—sharp corners, rapid changes in section size, undercuts and holes—should be avoided or minimized. Generous radiuses and chamfers should be used.
4. The impact of thermal stresses should be minimized by using the smallest section size consistent with other design constraints. The higher the symmetry the better (a cylinder will resist thermal shock better than a prism), and breaking up complex components into subcomponents with higher symmetry may help.
5. Components should be kept as small as possible—the strength and probability of failure at a given stress level are dependent on size; thus minimizing component size increases reliability.
6. The severity of impact should be minimized. Where impact (i.e., particulate erosion) cannot be avoided, low angle impacts ( $20^{\circ}$ – $30^{\circ}$ ) should be designed for. Note this is very different than the case of metals, where minimum erosion is at  $90^{\circ}$ .
7. Avoid surface and subsurface damage. Grinding should be done so that any residual grinding marks are parallel, not perpendicular, to the direction of principal tensile stress during use. Machining induced flaws are often identified to be the strength-limiting defect.

## 4 APPLICATIONS

The combinations of properties available in many advanced ceramics and glasses provide the designers of mechanical, electronic, optical, and magnetic systems a variety of options for significantly increasing systems performance. Indeed, in some cases the increase in systems performance is so great that the use of ceramic materials is considered an enabling technology. In the applications examples provided below the key properties and combinations of properties required will be discussed, as well as the resultant systems benefits.

### 4.1 Ceramics in Wear Applications

In the largest number of applications where modern ceramics are used in highly stressed mechanical applications, they perform a wear resistance function. This is true of silicon nitride used as balls in rolling element bearings, silicon carbide journal bearings or water pump seals, alumina washers in faucets and beverage

dispensing equipment, silicon nitride and alumina-based metal cutting tools, zirconia fuel injector components, or boron carbide sand blast nozzles, to cite some typical applications and materials.

Wear is a systems property rather than a simple materials property. As a systems property, wear depends upon what material is rubbing, sliding, or rolling over what material, upon whether the system is lubricated or not, upon what the lubricant is, and so forth. To the extent that the wear performance of a material can be predicted, the wear resistance is usually found to be a complex function of several parameters. Wear of ceramic materials is often modeled using an abrasive wear model where the material removed per length of contact with the abrasive is calculated. A wide variety of such models exist, most of which are of the form:

$$V \propto P^{0.8} K_{Ic}^{-0.75} H^{-0.5} N \tag{1}$$

where  $V$  is the volume of material worn away,  $P$  is the applied load,  $K_{Ic}$  is the fracture toughness,  $H$  is the indentation hardness, and  $N$  is the number of abrasive particles contacting the wear surface per unit length. Even if there are no external abrasives particles present, the wear debris of the ceramics themselves act as abrasive particles. Therefore, the functional relationships that predict that wear resistance should increase as fracture toughness and hardness increase are, in fact, frequently observed in practice.

Even though the point contacts that occur in abrasive wear produce primarily hertzian compressive stresses, in regions away from the hertzian stress field tensile stresses will be present and strength is, thus, a secondary design property. In cases where inertial loading or weight is a design consideration, density may also be a design consideration. Accordingly, Table 1, lists the fracture toughness, hardness, Young’s modulus, four-point modulus of rupture (MOR) in tension, and the density for a variety of advanced ceramic wear materials. Several successful applications of ceramics to challenging wear applications are described below.

**Bearings**

Rolling element bearings, for use at very high speeds or in extreme environments, are limited in performance by the density, compressive strength, corrosion resistance, and wear resistance of traditional high-performance bearing steels. The key screening test to assess a material’s potential as a bearing element is

**Table 1 Key Properties for Wear-Resistant Ceramics**

| Material                           | $K_{Ic}$ (MPa · m <sup>1/2</sup> ) | $H$ (kg/mm <sup>2</sup> ) | $E$ (GPa) | MOR (MPa) | $\rho$ (g/cm <sup>3</sup> ) |
|------------------------------------|------------------------------------|---------------------------|-----------|-----------|-----------------------------|
| Al <sub>2</sub> O <sub>3</sub> 99% | 3.9–4.5                            | 1900                      | 360–395   | 350–560   | 3.9                         |
| B <sub>4</sub> C                   | —                                  | 3000                      | 445       | 300–480   | 2.5                         |
| Diamond                            | 6–10                               | 8000                      | 800–925   | 800–1400  | 3.5                         |
| SiC                                | 2.6–4.6                            | 2800                      | 380–445   | 390–550   | 3.2                         |

rolling contact fatigue (RCF). RCF tests on a variety of alumina, SiC, Si<sub>3</sub>N<sub>4</sub>, and zirconia materials, at loads representative of high-performance bearings, demonstrated that only fully dense silicon nitride (Si<sub>3</sub>N<sub>4</sub>) could out-perform bearing steels.<sup>10</sup> This behavior has been linked to the high fracture toughness of silicon nitride, which results from a unique “self-reinforced” microstructure, combined with a high hardness. Additionally, the low density of silicon nitride creates a reduced centrifugal stress on the outer races at high speeds. Fully dense Si<sub>3</sub>N<sub>4</sub> bearing materials have demonstrated RCF lives 10 times that of high-performance bearing steel. This improved RCF behavior translates into DN (DN = bearing bore diameter in millimeters × shaft rpm) ratings for hybrid ceramic bearings (Si<sub>3</sub>N<sub>4</sub> balls running in steel races, the most common ceramic bearing configuration), about 50% higher than the DN rating of steel bearings. Other benefits of silicon nitride hybrid bearings include an order of magnitude less wear of the inner race, excellent performance under marginal lubrication, survival under lubrication starvation conditions, lower heat generation than comparable steel bearings, and reduced noise and vibration.

Another important plus for Si<sub>3</sub>N<sub>4</sub> is its failure mechanism. When Si<sub>3</sub>N<sub>4</sub> rolling elements fail, they do not fail catastrophically; instead they spall—just like bearing steel elements (though by a different microstructural mechanism). Thus, the design community only had to adapt their existing practices, instead of developing entirely new practices to accommodate new failure modes. The main commercial applications of silicon nitride bearing elements are listed in Table 2.

Cutting Tool Inserts

While ceramic cutting tools have been in use for over 60 years, it is only within the past two decades that they have found major application, principally in turning and milling cast-iron and nickel-based superalloys and finishing of hardened steels. In these areas ceramics based on aluminum oxide and silicon nitride significantly outperform cemented carbides and coated carbides. High-speed cutting tool tips can encounter temperatures of 1000°C or higher. Thus, a key property for an efficient cutting tool is hot hardness. Both the alumina and Si<sub>3</sub>N<sub>4</sub> families of materials retain a higher hardness at temperatures between 600 and 1000°C than either tool steels or cobalt-bonded WC cermets. The ceramics are also more chemically inert. The combination of hot hardness and chemical inertness means that the ceramics can run hotter and longer with less wear than

Table 2 Commercial Applications of Si<sub>3</sub>N<sub>4</sub> Hybrid Bearings

|                                            |                                                                                                                                                                                         |
|--------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Machine tool spindles                      | The first and largest application, its main benefits are higher speed and stiffness, hence greater throughput and tighter tolerances                                                    |
| Turbomolecular pump shaft                  | Presently the industry standard, the main benefits are improved pump reliability and marginal lubrication capability, which provides increased flexibility in pump mounting orientation |
| Dental drill shaft                         | The main benefit is sterilization by autoclaving                                                                                                                                        |
| Aircraft wing flap actuators               | Wear and corrosion resistance are the main benefits                                                                                                                                     |
| In-line skates/mountain bikes              | Wear and corrosion resistance are the main benefits                                                                                                                                     |
| Space Shuttle main engine oxygen fuel pump | Here, the bearing is lubricated by liquid oxygen. Steel bearings are rated for one flight; Si <sub>3</sub> N <sub>4</sub> hybrid bearings are rated for five.                           |

the competing materials. Historic concerns with ceramic cutting tools have focused on low toughness, susceptibility to thermal shock, and unpredictable failure times. Improvements in processing, together with microstructural modifications to increase fracture toughness have greatly increased the reliability of the ceramics in recent years

Alumina-based inserts are reinforced (toughened) with zirconia, TiC, or TiN particles or SiC whiskers. The thermal shock resistance of alumina–SiC<sub>w</sub> is sufficiently high, so that cooling fluids can be used when cutting Ni-based alloys. Silicon-nitride-based inserts include fully dense Si<sub>3</sub>N<sub>4</sub> and SiAlON's, which are solid solutions of alumina in Si<sub>3</sub>N<sub>4</sub>. Fully dense Si<sub>3</sub>N<sub>4</sub> can have a fracture toughness of 6–7 MPa · m<sup>1/2</sup>, almost as high as cemented carbides (~9 MPa · m<sup>1/2</sup>), a high strength (greater than 1000 MPa) and a low thermal expansion that yields excellent thermal shock behavior. Silicon nitride is the most efficient insert for the turning of gray cast iron and is also used for milling and other interrupted cut operations on gray iron. Because of its thermal shock resistance, coolant may be used with silicon nitride for turning applications. SiAlON's are typically more chemically stable than the Si<sub>3</sub>N<sub>4</sub>'s but not quite as tough or thermal shock resistant. They are mainly used in rough turning of Ni-based superalloys.

Ceramic inserts are generally more costly than carbides (1.5–2 times more), but their metal removal rates are ~3–4 times greater. However, that is not the entire story. Ceramic inserts also demonstrate reduced wear rates. The combination of lower wear and faster metal removal means many more parts can be produced before tools have to be indexed or replaced. In some cases this enhanced productivity is truly astonishing. In the interrupted single-point turning of the outer diameter counterweights on a gray cast-iron crankshaft a SiAlON tool was substituted for a coated carbide tool. This change resulted in the metal removal rate increasing 150% and the tool life increasing by a factor of 10. Each tool now produced 10 times as many parts and in much less time. A gas turbine manufacturer performing a machining operation on a Ni-based alloy using a SiAlON tool for roughing and a tungsten carbide tool for finishing required a total of 5 h. Changing to SiC-whisker-reinforced alumina inserts for both operations reduced the total machining time to only 20 min. This yielded a direct savings of \$250,000 per year, freed up 3000 h of machine time per year, and avoided the need to purchase a second machine tool.

### **Ceramic Wear Components in Automotive and Light-Truck Engines**

Several engineering ceramics have combinations of properties that make them attractive materials for a variety of specialized wear applications in automotive engines.

The use of structural ceramics as wear components in commercial engines began in Japan in the early 1980s. Table 3, lists many of the components that have been manufactured, the engine company that first introduced the component, the material, and the year of introduction. In some of these applications several companies have introduced a version of the component into one or more of their engines.

Many of these applications are driven by the need to control the emissions of heavy-duty diesels. Meeting current emissions requirements creates conditions within the engine fuel delivery system that increase wear of lubricated steel

**Table 3 Ceramic Wear Components in Automotive and Light-Truck Engines**

| Component                    | Engine Manufacturer | Engine Type | Ceramic                        | Year of Introduction |
|------------------------------|---------------------|-------------|--------------------------------|----------------------|
| Rocker arm insert            | Mitsubishi          | SI          | Si <sub>3</sub> N <sub>4</sub> | 1984                 |
| Tappet                       | Nissan              | Diesel      | Si <sub>3</sub> N <sub>4</sub> | 1993                 |
| Fuel injector link           | Cummins             | Diesel      | Si <sub>3</sub> N <sub>4</sub> | 1989                 |
| Injector shim                | Yanmar              | Diesel      | Si <sub>3</sub> N <sub>4</sub> | 1991                 |
| Cam roller                   | Detroit Diesel      | Diesel      | Si <sub>3</sub> N <sub>4</sub> | 1992                 |
| Fuel injector timing plunger | Cummins             | Diesel      | ZrO <sub>2</sub>               | 1995                 |
| Fuel pump roller             | Cummins             | Diesel      | Si <sub>3</sub> N <sub>4</sub> | 1996                 |

SI = spark-ignited engine.

against steel. One of these conditions is increased injection pressure, another is an increase in the soot content of engine lubricating oils. Strategic utilization of ceramic components within the fuel delivery systems of many heavy-duty truck engines has enabled the engines to maintain required performance for warranties of 500,000 miles and more. The fuel injector link introduced by Cummins in 1989 is still in production. Well over a million of these components have been manufactured. And many of these have accumulated more than a million miles of service with so little wear that they can be reused in engine rebuilds. In a newer model electronic fuel injector, Cummins introduced a zirconia timing plunger. The part has proved so successful that a second zirconia component was added to the timing plunger assembly several years later. Increasingly stringent emissions requirements for heavy diesels has increased the market for ceramic components in fuel injectors and valve train components. Many of these heavy-duty engine parts are manufactured at rates of 20,000 up to 40,000 per month.

Perhaps the largest remaining problem for this set of applications is cost. Ceramic parts are still more expensive than generally acceptable for the automotive industry. Reluctance of designers to try ceramic solutions still exists, but it is greatly diminishing thanks to the growing list of reliable and successful application of structural ceramic engine components.

## 4.2 Thermostructural Applications

Due to the nature of their chemical bond, many ceramics maintain their strength and hardness to higher temperatures than metals. For example, at temperatures above 1200°C, silicon carbide and silicon nitride ceramics are considerably stronger than any superalloy. As a consequence, structural ceramics have been considered and utilized in a number of demanding applications where both mechanically imposed tensile stresses and thermally imposed tensile stresses are present. One dramatic example is the ceramic (silicon nitride) turbocharger that has been in commercial production for automobiles in Japan since 1985. Over one million of these have been manufactured and driven with no recorded failure. This is a very demanding application, as the service temperature can reach 900°C, stresses at ~700°C can reach 325 MPa, and the rotor must also endure oxidative and corrosive exhaust gases that may contain erosion inducing rust and soot particles. Silicon nitride gas turbine nozzle vanes have been flying for

several years in aircraft auxiliary power units. Other applications include heat exchangers, and hot gas valving. Recently, ceramic matrix composites have been introduced as disks for disk breaks in production sports cars by two European manufacturers. A major future market for structural ceramics may be high-performance automotive valves. Such valves are currently undergoing extensive, multiyear fleet tests in Germany.

This class of applications requires a focus on the strength, Weibull modulus,  $m$  (the higher the  $m$ , the narrower the distribution of observed strength values), thermal shock resistance, and often the stress rupture (strength decrease over time at temperature) and/or creep (deformation with time at temperature) behavior of the materials. Indeed, as shown in Fig. 2, the stress rupture performance of current structural ceramics represents a significant jump in materials performance over superalloys.

The thermal shock resistance of a ceramic is a systems property rather than a fundamental materials property. Thermal shock resistance is given by the maximum temperature change a component can sustain,  $\Delta T$ .

$$\Delta T = \frac{\sigma(1 - \mu)}{\alpha E} \frac{k}{r_m h} S \quad (2)$$

where  $\sigma$  is strength,  $\mu$  is Poisson's ratio,  $\alpha$  is the coefficient of thermal expansion (CTE),  $E$  is Young's modulus,  $k$  is thermal conductivity,  $r_m$  is the half-thickness for heat flow,  $h$  is the heat transfer coefficient, and  $S$  is a shape factor totally dependent on component geometry.<sup>11</sup> Thus it can be seen that thermal shock resistance,  $\Delta T$ , is made up of terms wholly dependent on materials properties, dependent on heat transfer conditions, and on geometry. It is the role of the ceramic engineer to maximize the former and of the design engineer to maximize the later two terms. It has become usual practice to report the materials-related thermal shock resistance as the instantaneous thermal shock parameter,  $R$ , which is equal to

**Fig. 2** Stress rupture performance of nonoxide structural ceramics compared to superalloys (oxidizing atmosphere).

**Table 4    Calculated Thermal Shock Resistance of Various Ceramics**

| Material                                  | $\sigma$ (MPa) | $\mu$ | CTE (cm/cm K)         | $E$ (GPa) | $R$ (K) |
|-------------------------------------------|----------------|-------|-----------------------|-----------|---------|
| Al <sub>2</sub> O <sub>3</sub> (99%)      | 345            | 0.22  | $7.4 \times 10^{-6}$  | 375       | 97      |
| AlN                                       | 350            | 0.24  | $4.4 \times 10^{-6}$  | 350       | 173     |
| SiC (sintered)                            | 490            | 0.16  | $4.2 \times 10^{-6}$  | 390       | 251     |
| PSZ                                       | 1000           | 0.3   | $10.5 \times 10^{-6}$ | 205       | 325     |
| Si <sub>3</sub> N <sub>4</sub> (sintered) | 830            | 0.3   | $2.7 \times 10^{-6}$  | 290       | 742     |
| LAS (glass CERAMIC)                       | 96             | 0.27  | $0.5 \times 10^{-6}$  | 68        | 2061    |
| Al-titanate                               | 41             | 0.24  | $1.0 \times 10^{-6}$  | 11        | 2819    |

$$R = \frac{\sigma(1 - \mu)}{\alpha E}$$

(3)

The value of  $R$  for selected ceramics is presented in Table 4. Another frequently used parameter is  $R'$ , the thermal shock resistance where some heat flow occurs:  $R'$  is simply  $R$  multiplied by the thermal conductivity,  $k$ . For cases where heat transfer environments are complex, Ref. 12 lists 22 figures of merit for selecting ceramics to resist thermal stress.

**4.3    Corrosion Resistance**

Many advanced structural ceramics such as alumina, silicon nitride, or SiC have strong atomic bonding that yields materials that are highly resistant to corrosion by acidic or basic solutions at room temperature (the notable exception being glass or glass-bonded ceramics attacked by HF). This corrosion resistance has led to many applications. Carbonated soft drinks are acidic, and alumina valves are used to meter and dispense these beverages at refreshment stands. The chemical industry utilizes a wide variety of ceramic components in pumps and valves for handling corrosive materials. For example, the outstanding corrosion resistance of fully dense SiC immersed in a variety of hostile environments is given in Table 5. There are many cases where corrosion and particulate wear are superimposed, as in the handling of pulp in papermaking or transporting slurries in mineral processing operations, and ceramics find frequent application in such uses.

**Table 5    Weight Loss of Fully Dense SiC in Acids and Bases**

| Reagent (wt %)                     | Test Temperature (°C) | Weight Loss (mg/cm <sup>2</sup> yr) |
|------------------------------------|-----------------------|-------------------------------------|
| 98% H <sub>2</sub> SO <sub>4</sub> | 100                   | 1.5                                 |
| 50% NaOH                           | 100                   | 2.5                                 |
| 53% HF                             | 100                   | <0.2                                |
| 85% H <sub>3</sub> PO <sub>4</sub> | 100                   | <0.2                                |
| 45% KOH                            | 100                   | <0.2                                |
| 25% HCl                            | 100                   | <0.2                                |
| 10% HF + 57% HNO <sub>3</sub>      | 25                    | <0.2                                |

Specimens submerged 125 to 300 h, continuously stirred.

4.4 Passive Electronics

The role of passive electronics is to provide insulation (prevent the flow of electrons) either on a continuous basis (as in the case of substrates or packages for microelectronics) or on an intermittent basis as is the case for ceramic capacitors (which store electric charge and hence need a high polarizability). These two applications constitute two of the largest current markets for advanced ceramics. For electronic substrates and packages key issues include the minimization of thermal mismatch stresses between the Si (or GaAS) chip and the package material (so the CTE will be important) and dissipation of the heat generated as electrons flow through the millions of transistors and resistors that comprise modern microelectronic chips; hence the thermal conductivity is a key property. All other things being equal, the delay time for electrons to flow in the circuit is proportional to the square root of the dielectric constant of the substrate (or package) material. Additionally, the chip or package must maintain its insulating function, so resistivities of  $>10^{14}$  are required. Most high-performance packages for computer chips are alumina. With the advent of microwave integrated circuits (e.g., cell phones) aluminum nitride substrates are beginning to be utilized for high thermal conductivity. The environmental drawbacks to machining BeO has tended to favor the use of AlN to replace or avoid the use of BeO. Synthetic diamond is an emerging substrate material for special applications. Isotopically “pure” synthetic, single-crystal diamond has values of thermal conductivity approaching 10,000 W/mK. Typical values of the above properties for each of these materials is given in Table 6, along with selected properties of silicon for comparison. For design purposes exact values for specific formulations of the materials should be obtained from the manufacturers.

Over a billion ceramic capacitors or multilayer ceramic capacitors (MLCC) are made every day.<sup>13</sup> Since electrons do not flow through capacitors, they are considered passive electronic components. However, the insulators from which ceramic capacitors are made polarize thereby separating electric charge. This separated charge can be released and flow as electrons, but the electrons do not flow through the dielectric material of which the capacitor is composed. Thus, the materials parameter, which determines the amount of charge that can be stored, the dielectric constant,  $k$ , is the key parameter for design and application. Table 7 lists the approximate dielectric constant at room temperature for several families of ceramics used in capacitor technology. The dielectric constant varies

Table 6 Key Properties for Electronic Substrates and Packages

| Material                             | CTE ( $10^{-6}/K$ ) | Therm. Cond.<br>(W/mK) | Resistivity | Dielectric<br>Const. |
|--------------------------------------|---------------------|------------------------|-------------|----------------------|
| Al <sub>2</sub> O <sub>3</sub> (96%) | 6.8                 | 26                     | $>10^{14}$  | 9.5                  |
| Al <sub>2</sub> O <sub>3</sub> (99%) | 6.7                 | 35                     | $>10^{14}$  | 10                   |
| AlN                                  | 4.5                 | 140–240                | $>10^{14}$  | 9                    |
| BeO                                  | 6.4                 | 250                    | $>10^{14}$  | 6.5                  |
| Diamond                              | 2                   | 2000                   | $>10^{14}$  | 5.5                  |
| Silicon                              | 2.8                 | 150                    |             |                      |

Note: CTE and thermal conductivity are at room temperature, and the dielectric constant is at 1 MHz.

**Table 7 Dielectric Constants for Various Ceramic Capacitor Materials**

| Material                                         | Dielectric Constant at RT |
|--------------------------------------------------|---------------------------|
| Tantalum oxide (Ta <sub>2</sub> O <sub>5</sub> ) | ~25                       |
| Barium titanate                                  | ~5,000                    |
| Barium–zirconium titanate                        | ~20,000                   |
| Lead–zirconium titanate (PZT)                    | ~2,000                    |
| PZT with W or Mg additives                       | ~9,000                    |
| Lead magnesium niobate (PMN)                     | ~20,000                   |
| Lead zinc niobate (PZN)                          | ~20,000                   |

with both temperature and frequency. Thus, for actual design precise curves of materials performance over a relevant range of temperatures and frequencies are often utilized. Many ceramics utilized as capacitors are ferroelectrics, and the dielectric constant of these materials is usually a maximum at or near the Curie temperature.

**4.5 Piezoceramics**

Piezoceramics are a multi-billion dollar market.<sup>14</sup> Piezoceramics are an enabling material for sonar systems, medical ultrasonic imaging, micromotors and micro-positioning devices, the timing crystals in our electronic watches, and numerous other applications. A piezoelectric material will produce a charge (or a current) if subjected to pressure (the *direct* piezoelectric effect) or, if a voltage is applied, the material will produce a strain (the *converse* piezoelectric effect). Upon the application of a stress, a polarization charge,  $P$ , per unit area is created that equals  $d\sigma$ , where  $\sigma$  is the applied stress and  $d$  is the piezoelectric modulus. This modulus, which determines piezoelectric behavior, is a third-rank tensor<sup>15</sup> that is thus highly dependant on directions along which the crystal is stressed. For example, a quartz crystal stressed in the [100] direction will produce a voltage, but one stressed in the [001] direction will not. In a polycrystalline ceramic the random orientation of the grains in an as-fired piezoceramic will tend to minimize or zero out any net piezoelectric effects. Thus, polycrystalline piezoceramics have to undergo a postsintering process to align the electrically charged dipoles within the polycrystalline component. This process is known as poling and it requires the application of a very high electric field. If the piezoceramic is taken above a temperature, known as the Curie temperature, a phase transformation occurs and piezoelectricity will disappear. The piezoelectric modulus and the Curie temperature are thus two key materials selection parameters for piezoceramics.

The ability of piezoceramics to almost instantaneously convert electrical current to mechanical displacement, and vice versa, makes them highly usefull as transducers. The efficiency of conversion between mechanical and electrical energy (or the converse) is measured by a parameter known as the coupling coefficient. This is a third key parameter that guides the selection of piezoelectric materials.

Although piezoelectricity was discovered by Pierre and Jacques Curie in 1880, piezoceramics were not widely utilized until the development of poly-

crystalline barium titanate in the 1940s and lead zirconate titanates (PZT) in the 1950s. Both of these materials have high values of  $d$  and thus develop a high voltage for a given applied stress. PZT has become widely used because in addition to a high  $d$  value, it also has a very high coupling coefficient. Sonar, in which ultrasonic pulses are emitted and reflected “echoes” are received, is used to locate ships, fish, and map the ocean floor by navies, fishermen, and scientists all over the globe. Medical ultrasound utilizes phased arrays of piezoceramic transducers to image organs and fetuses noninvasively and without exposure to radiation. A relatively new application that has found significant use in the microelectronics industry is the use of piezoceramics to drive micropositioning devices and micromotors. Some of these devices can control positioning to a nanometer or less. Piezoceramic transducers combined with sophisticated signal detection and generation electronics to create “active” noise and vibration damping devices. In such devices the electronics detect and quantify a noise spectrum and then drive the transducers to provide a spectrum 180° out of phase with the noise, thereby, effectively canceling it.

Many of the current high-performance applications of piezoceramics are based on proprietary modifications of PZT, which contain additions of various dopants or are solid solutions with perovskite compounds of Pb with Mg, Mn, Nb, Sn, Mo, or Ni. Table 8, lists the range of several key piezoceramic selection parameters for proprietary PZT compositions from one manufacturer.

4.6 Transparencies

Transparent ceramics (which include glasses, single-crystal, and polycrystalline ceramics) have been used as optical transparencies or lenses for millennia. Glass windows were in commercial production in first century Rome, but it was not until the 1800s, with the need for precision optics for microscopes, telescopes, and ophthalmic lenses, that glasses and other optical materials became the object of serious scientific study. As noted in the introduction, progress in glass science and technology, coupled with lasers, has led to the current broadband digital data transmission revolution via optical fibers. Various ceramic crystals are used as laser hosts and specialty optical lenses and windows. A significant fraction of supermarket scanner windows combine the scratch resistance of sapphire (single-crystal alumina) with its ability to transmit the red laser light that we see at the checkout counter. While such windows are significantly more costly than glass, their replacement rate is so low that they have increased profitability for several supermarket chains. For the same reason the crystal in many high-end watches are scratch-resistant manmade sapphire. Polycrystalline translucent (as opposed to fully transparent) alumina is used as containers (envelops) for the sodium vapor lamps that light our highways and industrial sites.

Table 8 Key Properties for PZT Based Piezoceramics

| Material | Piezoelectric Modulus, $d_{33}$ | Curie Temp (°C) | Coupling Coefficient, $k_{33}$ |
|----------|---------------------------------|-----------------|--------------------------------|
| A        | $226 \times 10^{-12}$ m/V       | 320             | 0.67                           |
| B        | $635 \times 10^{-12}$ m/V       | 145             | 0.68                           |
| C        | $417 \times 10^{-12}$ m/V       | 330             | 0.73                           |

Not all windows have to pass visible light. Radar or mid- to far-infrared transparencies look opaque to the human eye but are perfectly functional windows at their design wavelengths. The most demanding applications for such transparencies is for the guidance domes of missiles. Materials that can be used for missile radomes include slip-cast fused silica, various grades of pyroceram (glass ceramics), and silicon-nitride based materials. Infrared (IR) windows and missile domes include  $\text{MgF}_2$  and  $\text{ZnSe}$ . Requirements exist for having missile guidance domes that can transmit in the visible, IR, and radar frequencies (multi-mode domes). Ceramic materials that can provide such functionality include sapphire and aluminum oxynitride spinel (AlON). In addition to optical properties missile domes must be able to take high aerothermal loading (have sufficient strength) and be thermal shock resistant (a high-speed missile encountering a rain cloud can have an instant  $\Delta T$  of minus several hundred degrees kelvin).

Key properties for visible and IR optical materials include the index of refraction,  $n$  (which will be a function of wavelength), and absorption or loss. For radar transparencies key parameters are dielectric constant (which can be thought of as analogous to the index of refraction) and dielectric loss.

## 5 INFORMATION SOURCES

### 5.1 Manufacturers and Suppliers

There are hundreds of manufacturers of advanced ceramics and glasses. Locating ones that either already have the material that is needed, and can produce it in the configuration required, can be a daunting task. There are two resources published annually that make this task much easier. The American Ceramic Society publishes a directory of suppliers of materials, supplies, and services that can help locate such information quickly. It is called *Ceramic Source*. This directory can also be accessed on the worldwide web at [www.ceramics.org](http://www.ceramics.org). A similar *Buyers Guide* is published by *Ceramic Industry Magazine*, and this can also be viewed online at [www.ceramicindustry.com](http://www.ceramicindustry.com). Once a likely source for your need has been identified, a visit to the supplier's web site can often provide a great deal of background information and specific data, which can make further contacts with the supplier much more meaningful and informative.

### 5.2 Data

Manufacturer's literature both hardcopy and posted on the worldwide web, are invaluable sources of data. The handbooks, textbooks, and encyclopedias listed below are also excellent sources of data. However, before committing to a finalized design or to production, it is advisable to develop one's own test data in conformance with your own organization's design practice. Such data should be acquired from actual components made by the material, processing route, and manufacturer that have been selected for the production item.

ASM, *Ceramics and Glasses, Vol 4, Engineered Materials Handbook*, ASM International, Materials Park, OH, 1991.

J. F. Shackelford, W. Alexander, and J. Park (eds.), *Materials Science and Engineering Handbook*, 2nd ed., CRC Press, Boca Raton, FL, 1994.

- C. X. Campbell and S. K. El-Rahaiby (eds.), *Databook on Mechanical and Thermophysical Properties of Whisker-Reinforced Ceramic Matrix Composites*, Ceramics Information Analysis Center, Purdue University, W. Lafayette, IN, and The American Ceramic Society, Westerville, OH, 1995.
- R. J. Brook (ed.), *Concise Encyclopedia of Advanced Ceramic Materials*, Pergamon Press, Oxford, 1991.

### 5.3 Standards and Test Methods

To reliably design, procure materials, and assure reliability, it is necessary to have common, agreed-upon, and authoritative test standards, methods, and practices. Institutions such as the American Society for Testing of Materials (ASTM), the Japanese Institute for Standards (JIS), the German Standards Organization (DIN), and the International Standards Organization (ISO) all provide standards for their various constituencies. The following are a sampling of standards available from the ASTM and JIS for advanced ceramics and ceramic matrix composites. One can reach these organizations at the following addresses.

American Society for Testing Materials (ASTM), 100 Barr Harbor Drive, Conshohocken, PA 19428-2959:

- C-177-85(1993), Test Method for Steady State Heat Flux and Thermal Transmission by Means of the Gradient-Hot-Plate Apparatus
- C-1161-90, Test Method for Flexural Strength of Advanced Ceramics at Ambient Temperature
- C-1211-92, Test Method for Flexural Strength of Advanced Ceramics at Elevated Temperature
- C-1259-94, Test Method for Dynamic Young's Modulus, Shear Modulus and Poisson's Ratio for Advanced Ceramics by Impulse Excitation of Vibration
- C-1286-94, Classification for Advanced Ceramics
- C-1292-95A, Test Method for Shear Strength of Continuous Fiber-Reinforced Ceramic Composites (CFCCs) at Ambient Temperatures
- C-1337-96, Test Method for Creep and Creep-Rupture of CFCCs under Tensile Loading at Elevated Temperature
- C-1421-99, Standard Test Method for Determination of Fracture Toughness of Advanced Ceramics at Ambient Temperature
- C-1425-99, Test Method for Interlaminar Shear Strength of 1-D and 2D CFCCs at Elevated Temperature
- E-228-85(1989), Test Method for Linear Thermal Expansion of Solid Materials with a Vitreous Silica Dilatometer
- E-1269-94, Test Method for Determining Specific Heat Capacity by Differential Scanning Calorimetry
- E-1461-92, Test Method for Thermal Diffusion of Solids by the Flash Method

The Japanese Standards Association, 1-24, Akasaka 4, Minato-ku, Tokyo 107 Japan:

- Testing Methods for Elastic Modulus of High Performance Ceramics at Elevated Temperatures; JIS R 1605-(1989)
- Testing Methods for Tensile Strength of High Performance Ceramics at Room and Elevated Temperatures; JIS R 1606-(1990)
- Testing Methods for Fracture Toughness of High Performance Ceramics; JIS R 1607-(1990)
- Testing Methods for Compressive Strength of High Performance Ceramics; JIS R 1608-(1990)
- Testing Methods for Oxidation Resistance of Non-Oxide of High Performance Ceramics; JIS R 1609-(1990)
- Testing Methods for Vickers Hardness of High Performance Ceramics; JIS R 1610-(1991)
- Testing Methods of Thermal Diffusivity, Specific Heat Capacity, and Thermal Conductivity for High Performance Ceramics by Laser Flash Method; JIS R 1611-(1991)

In addition to testing standards, it is possible to obtain standard materials with certified properties to calibrate several of these new standards against your own tests. Such standard materials can be obtained from the National Institute of Science and Technology (NIST). For example, a standard material to calibrate ASTM C-1421-99 has just been made available. Materials standards are not available for all of the above tests.

#### 5.4 Design Handbooks

It has been widely recognized that procedural handbooks that provide methodology on how to design with advanced ceramics and which can provide high quality evaluated design data are sorely needed for ceramic materials. The ceramics matrix composites (CMCs) community has taken the initiative to begin the process of creating such a handbook for its constituency. The activity is sponsored by various U.S. governmental agencies including the Department of Defense, the Department of Energy, The Federal Aviation Administration, and the National Aeronautics and Space Administration and is entitled MIL-Handbook-17. This activity brings together materials suppliers, materials testers, designers, and end users who are engaged in developing a handbook that will provide design tools and guidance, provide guidelines on data generation, documentation, and use, and provide an authoritative source of design quality data. This is a work in progress and its completion is many years off, if ever. Nevertheless, much guidance in design and testing of advanced CMCs has already resulted from this activity. Progress can be followed by periodically accessing the handbook websites at <http://mil-17.udel.edu> or <http://www.materials-sciences.com/MIL17/>. Unfortunately, no similar activity exists for monolithic ceramics.

#### 6 FUTURE TRENDS

It has been estimated that in the United States advanced ceramics of the type discussed above are an over \$8-billion-dollar a year industry with a growth rate of ~8% per year.<sup>16</sup>

The largest segment of this growth will come from the electronics area. Not only will there be significant growth in the “traditional” roles of ceramics as insulators, packages, substrates, and capacitors, but structural ceramics will play a major role in the equipment used in semiconductor manufacturing. This trend will be especially driven by the resistance of ceramics such as SiC, AlN, silicon nitride, and alumina to the erosive and corrosive environments within high-energy plasma chambers used in single-wafer processing operations.

The intertwined global issues of energy sufficiency and environmental protection will see commercial use of advanced ceramics in energy systems as diverse as solid oxide fuel cells and pebble-bed modular reactors (nuclear). As more and more industries move toward “green” (pollution free) manufacturing, there will be growth in wear- and corrosion-resistant ceramics for industrial machinery. There will also be substantial growth potential for ceramic filters and membranes. One major environmentally driven opportunity will be particulate traps for diesel trucks and industrial power sources. This technology is just beginning to be commercialized, and it is certain to see rapid growth as emissions requirements for diesel engines grow more stringent. Not all progress in these areas will create increased markets for ceramics; some will reduce them. For example, the rapid growth of energy-efficient light-emitting diode technology for illumination will create a significant growth opportunity for producers of single-crystal SiC substrates and GaN materials. However, this will come at a cost to the ceramics industry of a significant decrease in glass envelopes for incandescent bulbs and fluorescent tubes. Another area of growth will be filters and membranes for filtration of hot or corrosive, or both, gases and liquids.

The explosive growth of fiber-optic- and microwave-based digital communications technology has produced significant opportunities and markets for advanced ceramics and glasses and will continue to do so into the foreseeable future.

Medical applications are sure to grow, both in the area of diagnostics and prosthetics.

At the entrance to the Pohang Steel complex in Pohang, Republic of Korea, is a wonderful sign. It proclaims; “Resources are Limited—Creativity is Unlimited.” This thought certainly applies to the global future of advanced ceramics. Creatively utilized advanced ceramics will effectively expand our resources, protect our environment, and create new technological opportunities. The potential opportunities go far beyond the few discussed in this chapter.

| <b>2 THE PROCESS</b>  | <b>444</b> | <b>REFERENCES</b>  | <b>456</b> |

### 1 INTRODUCTION

Locating information, especially information regarding the physical properties of materials, is often like doing a logic puzzle. First you have an explanation of what you are going to do with limited information. Then you are given a set of clues or data that are known. Starting with what you know, you sort information logically to get to the “correct answer.” When you first start solving the logic puzzle, it always seems there are too few clues. This tempts you to make assumptions such as “the character named Chris is female.” Making assumptions early in the process often means you end up with the wrong answer. When starting to look for data and other information about materials, it is easy to assume that the information must be in a specific tool or database. It is often easier to assume the data simply does not exist, that it must exist in a specified format to be useful, or that the information must be retrieved from the engineering literature. The two most insidious assumptions are that the information will be published in English and that to contain good data the information must have been published in the last 5 years (OK, maybe 10 years). Falling prey to these assumptions will mean much time is wasted both in the information search process and when developing novel materials.

To solve a logic puzzle, the puzzle solver will take multiple steps and often repeat those steps until the puzzle has been completed (see Fig. 1). The basic process is cyclic with a solution being reached when enough information has been gathered. The solution should always be double-checked before going to the answer key.

Luckily, when you are locating information to solve materials engineering problems you do not rely on just what you have in front of you. In fact, looking for unique data to help you solve your problem is the best way to deal with

## The solution

**Fig. 1** Solving a logic puzzle.

real-life logic puzzles, especially in materials science. Unfortunately, because you do not have to limit your quest for information to the description provided, the process is a bit more complicated though is similar to solving the logic puzzle. Table 1 shows a “logic” grid that information seekers use subconsciously. This grid shows three logic steps:

Know what your compound/material is and how it will be referred to in the literature.

Know what information is in each data source.

Learn how to use the indexes available in the data sources.

Looking for information is cyclic in nature, with steps being redone until the information needed is gathered (or until you are sure there is no information to find). The solution should be double-checked when possible by using multiple sources. The steps held in common when searching for any information are:

Define the question.

Set up a strategy to locate the needed information.

Use the resources you know best.

Go to less known resources when necessary.

Evaluate the quality of the data/information resource.

Start again, if needed, using the new information to help better define the question.

Know when the information gathered is enough (or probably all there is).

This chapter will discuss these steps in depth making recommendations that will help the materials engineer find data and information more easily and within

**Table 1 Resource Grid: Focus on Tools That May Have Information Needed—An Example**

| Question: What Is Thermal Conductivity of Diamonds?                                                                                                   |                                                                                                                                     |                                                                                                                                                      |                                                                                                                                                                                                                                    |

reasonable time spans and cost budgets. I will add some comments on how to work with information professionals effectively and some of the electronic resources that are available to help you keep current.

## 2 THE PROCESS

**Defining the Question.** What is it you really want to find? Too often the materials engineer limits his or her answer set by asking for what she or he thinks can be found rather than what he or she really wants and needs. Often this is due to time restraints because the information or data located in less used information sources are not as immediately understood or as quickly incorporated into projects as those found in more familiar resources. These issues need to be addressed up front in order to get the information you need as quickly as you need it. Figure 2 shows a simple question or search form to help materials engineers define their questions clearly and prepare for the information hunt. The *search request* is a sentence or short paragraph that clearly states what information you need. It helps the engineer to take a moment and write out the search request. This clarifies what information is needed as well as what information is already known. In addition, a written search request makes it easier to communicate with information professionals when their help is needed. *Important terms* are those words that will be used to find information in indexes and with search engines. This form is not static; additional terms should be added as the search for data progresses. Different tools use different terminology to refer to the same or similar topics. Also, different fields of study may use the same term differently. Finally, terminology and how it is applied changes over the years. In most databases, the indexing is not updated, so the searcher needs to be familiar with all possible indexing choices. Here are some examples of these issues.

- Search request

*What is the failure rate of polyethylene biomaterials*

- Important terms

biomaterial(s), biomedical material(s),  
biomedical device(s), synthetic  
biomaterial(s), biological structural  
material(s)

Specific device names

- CAS RNs; molecular formulas,  
alternative names.

Poly(ethylene)  
ethylene, polymers  
ethene, homopolymer  
selected trade names

9002-88-4

### Outline search strategy.

- Background resources:  
Kirk-Othmer (how long have they  
been used, what are some uses)
- Databases:  
1st -- BIOSIS, MEDLINE to find out  
where it is used and reported  
problems.  
2nd -- INSPEC, CA, Compendex to  
investigate in more depth material  
characteristics
- Limitations:  
human subjects only  
clinical trials acceptable

Fig. 2 Searching worksheet.

**Example 1: Spelling Variations**

Recently, a scientist wanted information about “eschelle spectroscopy.” When only nine abstracts were obtained with that phrase, I suggested we look at the spelling of “eschelle.” Two variant spellings were in one of the nine abstracts retrieved. “Eschelle” was in the title and “echelle” was in the indexing. With the alternative spelling over 100 citations were found allowing further specification to include ICP (inductively coupled plasma) as a technique. Twenty-one citations were found with very specific information relevant to the work being done.

Over the years, these types of instances have shown me to always think broadly when dealing with terminology or important information will be missed, especially in cross-disciplinary searches. In the print world, these spellings might have been relatively close to each other in the index, and serendipity would have played its role in finding information. In the online world the searcher has to think broadly enough to make up for this loss of serendipity. Alternative spellings, abbreviations, and acronyms should always be included in a search in order to retrieve good resources.

**Example 2: Terminology Changes over Time and Emphasis Varies by Discipline**

Biomaterials is a cross-disciplinary area of research. To be effective in developing materials, the materials engineer may need to refer to the medical literature, chemical databases, and biological resources as well as the more traditional engineering resources. How many resources might be needed will vary depending on the nature of the search and how comprehensive the results need to be. Beginning investigation may not need multiple sources or databases. Dealing with a process or material that may eventually need to be patented will definitely require searching in multiple sources to find prior art.

The concept of biomaterials seems to be well defined in the engineering community today. *The Biomedical Engineering Handbook* states: “A biomaterial is used to make devices to replace a part or a function of the body in a safe, reliable, economic, and physiologically acceptable manner.”<sup>1</sup> Another current definition of biomaterials is: “An engineering material suitable for use in situations where it may come into direct contact with the internal tissues of the body. Sometimes, biomaterials is used to refer to biological structural materials.”<sup>2</sup> Notice the difference in emphasis on how the material will be used. Biomaterials have been in use since the 1800s. As late as the 1970s biomaterials were more often referred to under the heading of biocompatible materials.<sup>3</sup> “Synthetic biomaterials can be referred to as biomedical materials to distinguish them from naturally occurring biomaterials.”<sup>4</sup>

The medical community refers to biomaterials as “any substance (other than a drug) synthetic or natural, that can be used as a system or part of a system that treats, augments, or replaces any tissue, organ or function of the body.”<sup>5</sup> Currently the medical community tends to use specific names for types of biomaterials as well as the applications of these materials rather than the general term biomaterials.

The chemical community, as usual, focuses on the compound or class of materials such as polymers, ceramics, and metals with biomaterials or biomedical materials being considered a use rather than a type of material.

All of these differences need to be taken into consideration as the literature is searched. In this example the following terms would be included as possible search points: biomaterial(s), biomedical material(s), biomedical device(s), synthetic biomaterial(s), biological structural material(s), as well as more specific terms and chemical names relating to the specific interest.

One area where differences in terminology are definitely a factor is in chemical names. This means it is a good idea to identify terms like the Chemical Abstracts Service Registry Number (CAS RN), common names, trade names, and IUPAC or CAS names. Which of these names you know will often help you choose what tool to use to find the information or data you need. Again, variations on the chemical names will need to be added as the search progresses. Polymers is one area where nomenclature is very tricky, partly due to the large number of trade names as well as to seemingly insignificant changes in the chemical makeup of the polymer.

### Example 3: Chemical Compounds and Chemical Classes

Polyethylene is listed as a nonaromatic hydrocarbon backbone polymer in *the Physical Properties of Polymer Handbook*.<sup>6</sup> A slight name variation is noticed in the online edition of the *CRC Handbook of Chemistry and Physics*—poly(ethylene)—with a broader class name given as polyalkenes.<sup>7</sup> These differences are not critical in the paper world but might be in an electronic database. *Chemical Abstracts* has called this material by several names over the years. In the 8th Collective Period it was referred to as “ethylene, polymers.” Starting with the 9th Collective Period it has been referred to as “ethene, homopolymer.” The registry number 9002-88-4 has over 4500 alternative names (many trade names). There are also 84 deleted registry numbers (or compounds that at one time were considered unique and have since been reviewed and found to be “ethene, homopolymer.”) There are at least 49 files available on STN International (a vendor of databases with scientific bibliographic and numeric information; more fully described at the end of the chapter), a searching system that has information about the compound with registry number 9002-88-4. Each of these files has different methods of inputting chemical and material names, and each will provide different types of information. BIOSIS (the online database devoted to biological literature, described in depth later in the chapter), when searching for “polyethylene” as a controlled term, has 997 (search done on 4/28/01) citations. However, on the STN system, registry numbers have been added to the BIOSIS indexing for chemical compounds listed in the title of the article. Using the registry number as a search term yielded 2706 additional citations. When these citations were reviewed, it became quickly obvious that trade names were often used to refer to the polymer in the BIOSIS file. Without searching the registry number, important information would have been missed and the materials engineer might have missed, an important possible use for the material being studied

or the fact that some other company has already gotten approval for clinical trials with a product. Missing information in either case will cost the company.

**Locating Needed Information.** Once the research area has been well defined, it is time to move onto the *search strategy*. There are three major decisions that need to be made. First, is background information needed? If so, what are the background resources that should be consulted to gather basic information relating to the project? If background information is not needed, it is possible that the appropriate background resources will provide leads as to what databases should be investigated.

Second, what databases (defined as a searchable source of information in paper or electronic format including data compilations, handbooks, and literature resources) will be appropriate to find the information you need. Do not limit the research to known databases in engineering. Materials science is cross disciplinary in nature. Literature databases in many other fields such as biology (BIOSIS), physics (INSPEC), medicine (MEDLINE) and chemistry (*Chemical Abstracts*) as well as Engineering Index (COMPENDEX) should all be consulted. The number of databases that need to be accessed depends on how comprehensive the information needs to be. These databases are discussed in more detail later in this chapter. Materials that may end up in a patent need to be researched in great depth using both print and online databases. Special attention to patent resource files such as Derwent and the U.S. Patent files will be needed when preparing for patent processes.

When dealing with data sources (handbooks, electronic databases, etc.), it is also wise to consider not only those that are well known in materials science but also those in related disciplines. Though the data needed may be in different formats or measured in different manners, they can still be useful when designing new materials. Chapter 16 discusses data sources and search strategies that vary depending on the type of data needed in considerable depth.

Third, are there any limitations that need to be considered before going into the resources? Often researchers provide themselves with false limitations such as:

If the data is not available in an electronic format, then it doesn't exist.

Anything published before 1960 is not accurate.

One example is the vast amount of information available through Gmelin, short for *Gmelins Handbuch der Anorganischen Chemie*, which contains data on inorganic compounds and materials collected and published from the 1800s. Though the data are old, and further testing may be needed with today's analytical tools, the data are well researched in considerable depth and are sometimes the only data available. This tool has been made easier to use with the advent of Crossfire, which provides an extensive index with some of the property information in an electronic format. This tool may provide helpful starting points for more in-depth investigation. For example, Gmelin has six volumes dealing with molybdenum and compounds of molybdenum. Additional information can be found in other volumes as well. The 4-page section in the main volume

(published in 1935) detailing the thermal properties of elemental Mo included data on the specific heat measured from  $-253$  to  $1500^{\circ}\text{C}$ . Referenced data for these results go back to *Annales der Chimie et de Physique* in 1840. The Gmelin database, as loaded on STN, cites 44 measurements of heat capacity at a constant pressure and 10 measurements of heat capacity at a constant volume. One of the later measurements comes from *Physical Review B*, vol 44, 1991. Over 150 years of literature is covered in this database.

Limitations that will be helpful include project deadlines, details about the physical state of the materials being researched, material characteristics and physical properties that are critical to the project goals, and cost limitations. Deadlines and cost limitations become very important when the information specialist is consulted. Generally speaking the sooner the deadline the more expensive the search process will be.

**Using Best Known Resources First.** Taking the time to be open to different possibilities means the results of the process may be very different than the expected “correct answer” foreseen at the beginning of the process. Also, there are a vast number of data resources to be considered, each with its own quirks. A busy materials engineer does not have the time to learn how to use them all. Take a look at Chapter 16 to get an idea of the many databases and information sources available. The best and most knowledgeable materials engineer cannot possibly know more than a few of these resources well. However, now that many handbooks have electronic versions and databases are developing more user-friendly search interfaces, it is possible to have access at your desktop to many familiar handbooks and databases. Searching for clues to information not as readily available can be done without leaving your office by using both paper and electronic resources.

Each materials engineer should develop his or her own desktop library. This collection will be a combination of print and electronic resources with which the materials engineer is familiar. Electronic versions of familiar resources should be used when the electronic interface adds to the value of the resource or space does not allow for the printed item. The desktop library should be considered both a fast answer resource as well as a place to find more clues to solve the physical property logic puzzle. The desktop library should contain at least one major handbook as well as some specialized handbook or data compilations. How many of these resources are used will depend on the space and funds available.

With the advent of online encyclopedias, the Desktop Library can contain a good resource for background information. Look at the electronic version of *Ullmann's Encyclopedia of Industrial Chemistry* and *Kirk-Othmer Encyclopedia of Chemical Technology* as possible resources. Access to the primary literature can be gained through full-text journals with or without use of indexing and abstracting tools. Two useful journals, now available full text are *Journal of Physical and Chemical Reference Data* (<http://ojps.aip.org/jpcrd/>) and *Journal of Chemical & Engineering Data* (<http://pubs.acs.org/journals/jceaax/index.html>). Both of these titles have been terrific data sources for many years.

Three hard copy handbooks (which can also be accessed electronically) that provide both basic information and leads to more extensive resources come to

mind—*Perry's Chemical Engineers' Handbook*, *Engineering Handbook* by Dorf, and *CRC Handbook of Chemistry and Physics*. Several materials-related handbooks are also useful resources—*Materials Handbook* by Brady and Clauser and the *CRC Materials Science and Engineering Handbook*. These are only a few of the titles available. The materials engineer should find the handbook(s) that fits his or her needs best. Once the more general handbooks have been selected, more specific subject/project-related handbooks are helpful. For example, an excellent resource in physical property information for polymer science is the *Physical Properties of Polymers Handbook* by James E. Mark, published by the American Institute of Physics. Notice that the handbooks mentioned are from a variety of disciplines that might be of use to a materials engineer.

The resources chosen should include basic information needed on a regular basis as well as charts and tables of information that might prove useful. For example, the *CRC Handbook of Chemistry and Physics* has very familiar tables of basic property information for organic and inorganic materials. But, unused by many, is the wealth of tables on many topics of interest to the materials engineer. I have already mentioned the Glass Transition Temperature for Selected Polymers. This table, by Robert B. Fox, has properties that were determined for the purpose of generating this table. Many tables are compilations of data from several sources, and the editors of the handbook are careful to note what resources were used. A good example of this is another table in the same section—Dielectric Constant of Selected Polymers. This table references three sources:

1. Gray, D. E., Ed., *American Institute of Physics Handbook*, 3rd ed., McGraw-Hill, New York, 1972, p. 5–132.
2. Anderson, H. L., Ed., *A Physicist's Desk Reference*, American Institute of Physics, New York, 1989.
3. Brandrup, J., and Immergut, E. H., *Polymer Handbook*, 3rd ed., Wiley, New York, 1989.

This reference list provides several pieces of information. First, it provides references to sources that may have more detailed information than that provided in this table (including the analytical methods used to generate the data). Second, they state the approximate “age” of the information. Because the dates are all prior to 1989, it becomes probable that additional information is available in the primary literature, in more current handbooks such as the *Physical Properties of Polymers Handbook* mentioned earlier, or in later editions of the handbooks referenced. Third, the references provide you with evaluative information. Knowing that the data has been in the published literature adds additional credence similar to peer review for other types of scientific literature. This is critical, as many online web pages with physical data on various compounds and materials do not tell you how the information is obtained, what the experimental conditions are, or even the purity of the material being tested. Starting with the known resource such as a favorite handbook, a physical property database, or a full-text journal, can lead to quicker results and very complete answers. With so

many handbooks and data compilations available at the desktop, it is important for the materials engineer to make the following decisions on what to include based on the following recommendations:

Include materials in your desktop library that you will use often. Know how to use your desktop library well.

Include items that have the type data or information needed routinely. Find out what is included in each resource as well as what limits (i.e., only data from patents is included) have been placed on inclusion.

Include items where access methods, such as indexing, table of contents, and online search options, are easy to use.

Include authoritative resources with good literature references and clearly noted experimental conditions.

***Going beyond Desktop.*** Once the familiar resources have been exhausted, it is time to consider outside help. Obviously, if you found the information you need and you are relatively certain you do not need additional verification, the search can stop at any time. However, if the desktop library has not led to the information you need or the project is being considered for publication or patenting, it is time to see the information expert in your organization.

The structure for getting information varies in each organization. It is important to understand the information climate of your organization. Some expect the materials engineer to find it all on their own. Some feel looking for information is not an effective use of the materials engineer's time and expects all such research efforts to be turned over to an information specialist. Most organizations have information centers, libraries, or reading rooms. Smaller companies or colleges may have limited access to information resources and external libraries or information brokers must be used. Many of the larger organizations will have information specialists or librarians. Smaller organizations may not have specialists in the area you are working, however, information professionals are all specialists in data organization and retrieval. So, even if they do not have the subject expertise you would like, they will often be able to help you use the tools effectively.

When to use these resources will depend on the information need. Find out what is preferred in your organization and do not limit your exploration to what the folks in your direct department do unless it is the best way for you to find the information you need. Often there are resources outside the department that will also help. In some places use of these external resources are not encouraged as there is a cost attached. In that case, try to weigh what the cost will be if the information needed is not found—e.g., millions of dollars spent on developing a product that someone else patented 2 years ago—against the cost of a good information search.

Many standard resources are now available to the engineer electronically and can be incorporated into the desktop library discussed previously. A cautionary note here. Make sure proper training on the use of even the basic resources is taken. As mentioned before, even the simplest of resources could have a wealth of information an engineer is not aware of because they have not used it to its fullest capacity. A tool you have used throughout your professional life may

have more information than you thought or may be used in different ways for better results. As electronic resources become more prevalent, the method of use may change from year to year, and a resource you knew how to use last month may have a new interface this month. The information professional is the expert on how to use information products. Information specialists and librarians generally enjoy showing the researcher and engineer how to use resources to their fullest capabilities. Many organizations will have routine training opportunities for those resources that are of the most use to their employees. Taking the time to learn these resources well will not only save you considerable amount of time later but the training opportunities will give you a chance to get to know the information staff at the organization. Then, when you need their help, they may already know what you are working on. This can speed up the process considerably. One additional note, some engineers are not comfortable with sharing their ideas at an early stage. Be assured information professionals know that confidentiality is an important part of their work. Your queries will not be shared with others.

Find out who the information gatekeeper is within your immediate organization. Sometimes there is a person who enjoys working with information who can guide you to the best resources and the best information specialist or librarian for your specific needs. In smaller organizations the information gatekeeper may indeed be the only information specialist available.

Always make use of internal resources first. Use the corporate library or information center as the first stop after exhausting your desktop library and your department's information gatekeeper. **Do not make the web your first stop outside your department!** This does not mean to ignore valuable resources that are available electronically through the Internet, such as the NIST databases and the many fine reference tools available. Rather it means use known resources, including your organization library and librarians (information center and information specialists), and purchased and attributed data sources accessed through the Internet before searching the highly disorganized web. The web contains vast amounts of information. However much of it has no attribution and little of it is organized so that information can be easily found. Anyone can post a page to the web for any reason. No quality check required. One excellent Internet resource is product information available in fact sheets and material safety data sheets (MSDS). As these are part of how a company markets its items, they should contain reliable information. At my institution, I tell students that when it is time to use the web, start at the library's home page where the librarians have already sorted through the web resources available and found some of the better ones to recommend. Also, the home page is where links are made to those electronic resources with web interfaces that the library purchases for students and faculty use.

After exhausting internal resources, find out what external organizations your company uses at a fee to get the information you need. If your organization has a library or information center, this may be transparent, i.e., the information center will provide the information to you by going to an outside organization. These services are called InterLibrary Loan (ILL) or document delivery by the library world. If your organization does not have such a service, it may have purchased information research skills through information consultants or bro-

kers. If it has done so, these consultants are most likely aware of the general needs for projects within your organization and may have specialized training in retrieving information applicable to your needs.

It is a good idea to determine what local colleges or universities have agreements with your organization that will allow you to use their collections. Unless you have a large library, browsing through a university research collection can be a fruitful way to gather information. For a small organization without internal information resources, local academic libraries are critical.

Academic libraries are the storehouse of information for the research community. However, this does not mean this information is accessible to every one. Public colleges and universities usually have some mandate to provide access to their collections and perhaps some services to residents of the state. What the limits of this access are will vary. Private academic communities do not have any obligation to provide such access, although many do. In either case, access methods and procedures will vary:

1. Check with the company library to find out if access to collections has been purchased. Academic libraries may be willing to allow members of local organizations to check out materials from their library upon purchase of a library card. Also, many companies do have ILL agreements that allow the company library to request copies of materials.
2. See if the reference services are available to noncommunity members. Generally a limited amount of reference service is available to the public, but this is not always the case. Reference staff like to help people find information. Being polite and friendly, asking interesting questions, understanding you are a guest, using services during slow times of the academic year, as well as being from an organization that supports the university can all mean your reference queries are taken seriously.
3. Determine what resources are accessible by noncommunity members. It used to be that anyone allowed in the door could use the paper copy *Engineering Index*. Now that the tool is in electronic format there may be restrictions on use for noncommunity members due to licensing agreements or searching costs.
4. Some academic libraries offer a fee for service arrangement. These can be very important to small companies. The costs are usually set up to recover any out-of-pocket expenses as well as some amount for the librarians' time.
5. Be aware that collections, electronic resources, and services cost money. If your company is relying on a local academic library, remember to offer assistance financially. This can often be done through Friends of the Library organizations, paying for research services, or by providing research funding (though this route will not get funding directly to the library).

**Evaluating Data/Information Resource.** One of the themes running through this chapter has been quality of information resources. This quality is seen by both the way the resources are organized and the value and quality of

information or data retrieved from the resources. Knowing how to evaluate information for quality is critical. It is important because bad data/information leads to poorly designed materials and bad products. For example, the shuttle *Challenger* disaster could have been avoided if better data on the stress and temperature factors affect the rubber rings had been incorporated into the design specifications.

There are several ways to evaluate the information you find. First, look at the quality of the resource being used. Handbooks that have been around for many editions and printings will generally have time-tested information. Property data from a well-know handbook is always better than a value found on some web page without any attribution. Peer-reviewed journal articles may provide better data than trade publications. Second, data that has experimental parameters defined is always better than “naked” information. The more known about how the information was collected the better. Third, if the person preparing the data source has not provided information on how it was collected or who measured it, it should only be used with caution. Fourth, use caution with information obtained from web pages. Remember that anyone can put up a web page. There is no requirement that data on a web page be accurate. Check the page out. Is there an author specified? Was the information put up by an unbiased organization? If the page is from a university, is the author a researcher or a student doing a class project? If the information is from a company, is it trying to sell you something?

It is the materials engineer’s responsibility to evaluate the information. The best scenario is to have multiple sources of information to quality check. This is rarely possible, and, sometime when it is, further checking many find that the data from multiple secondary resources came from the same primary resource. So the data and information must always be used within context and with care. Sometimes that means starting again because the data or information is suspect.

***Redefining the Question Using New Information.*** Starting again does not mean starting over. Usually there has been some information gathered that allows the materials engineer to refine the search question either more broadly or more narrowly. If no data has been found, broaden the topic and see if related information can be used. Can other properties be used to provide information if the specific one needed is not reported? When too much information has been found, narrow the topic wisely. Again, do not assume you want to narrow the scope by using only familiar resources. Sometimes the narrowing needs to be done by using resources outside the field that specialize in the information needed. Remember information specialists and librarians are experts in refining the search question.

***Knowing When Information Gathered Is Enough.*** Unlike a logic puzzle, data research does not always have an answer. Sometimes there is no data. For the researcher trying to delve into a new area, this might be wonderful. For the materials engineer trying to modify an existing material, this can be annoying. However, after you have broadened the search, after you have found related information but not exactly what you want, and after an information professional states the information does not appear to be the *published* literature, then it is

time to call on colleagues (if you have not before). Then searching the web might bring up a new lead. Or then it may simply be time to stop and go with what you have. Only the materials engineer can make that decision.

### 3 DATABASES

***Big Five Literature Databases.*** All of the major science literature databases provide indexing and abstracting of information from the primary literature from around the world. All contain full bibliographic information that is retrieved through subject indexing and free text searching of titles and abstracts. Each database contains some references to non-English language materials. The types of primary literature covered vary by discipline. All of the databases are available through major database vendors such as DIALOG, STN International, OCLC FirstSearch, Axiom (from IOP), and OVID. Many also have front ends and web search engines direct from the publisher. Different search features are available through different search interfaces. Most databases include title, abstract, indexing, and references. Many provide links to full-text information. The most up-to-date information about access options can be found on the databases or database vendors home pages. One way to evaluate which database to use is to look at the list of titles covered in a particular database. Note which titles are in a database “cover to cover” (i.e., all articles are entered) and which are selectively added.

1. ***BIOSIS—Biological Abstracts.*** BIOSIS, Two Commerce Square, 2001 Market Street, Suite 700, Philadelphia, PA 19103-7095. Phone: 1-800-523-4806 or +1-215-587-4800. Fax: +1-215-587-2016. Web: <http://www.biosis.org>. E-mail: [info@mail.biosis.org](mailto:info@mail.biosis.org). Indexes and abstracts in the biological, biochemical, and life sciences articles, books, dissertations, and conference proceedings. It has an extensive biological classification scheme. Available through most major database vendors. An added feature through STN: addition of CAS registry numbers to the indexes for compound listed in the article title. An excellent resource for biomaterials.

2. ***INSPEC—Physics Abstracts, Electrical and Electronics Abstracts, Computer and Control Abstracts.*** Institute for Electrical Engineers, Michael Faraday House, Six Hills Way, Stevenage, Herts, SG1 2AY, United Kingdom. Phone: (+44) 1438/313311, US 732-321-5575. Fax: (+44) 1438/742840, US 732-321-5702. E-mail: [inspec@iee.org.uk](mailto:inspec@iee.org.uk), or [inspec@inspecinc.com](mailto:inspec@inspecinc.com). 1969 to present. International in scope, the database contains over 2 million records for articles, conference proceedings, and books. The materials engineer should use this database to access information, pertaining to the physical properties of materials, in areas of physics, polymers, ceramics, computational methods, and biophysics. An interesting feature of this database is the element and physical property fields that can allow the materials engineer to specify what type of chemical components are discussed in the primary literature. An excellent resource for information on solid-state materials.

3. ***MEDLINE—Index Medicus.*** National Library of Medicine, MEDLARS Management Section, 8600 Rockville Pike, Bethesda, MD 20894. Phone: 1-800-638-8480. Fax: +1-301-496-0822. Web: <http://www.nlm.nih.gov>. E-

mail: mms@nlm.nih.gov. Indexes and abstracts the fields of medicine, nursing, dentistry, veterinary medicine, the health care system, and the preclinical sciences. MEDLINE contains bibliographic citations and author abstracts from more than 4000 biomedical journals published in the United States and 70 other countries. Available through many database vendors and directly (at no cost) from the National Library of Medicine. PubMed also provides access and links to the integrated molecular biology databases included in NCBI's Entrez retrieval system. These databases contain DNA and protein sequences, 3-D protein structure data, population study data sets, and assemblies of complete genomes in an integrated system.<sup>8</sup>

4. *CAS—Chemical Abstracts and the Registry File*. Chemical Abstract Service, 2540 Olentangy River Road. Columbus, Ohio 43202. Phone: 1-614-447-3700. Fax: 1-614-447-3767. Web: <http://www.cas.org>. Email: [help@cas.org](mailto:help@cas.org). CAS indexes and abstracts in chemistry, biochemistry, and other chemical sciences papers, books, conference proceedings, patents, technical reports, and dissertations worldwide (1907 to current). Chemical name, chemical structure, genome, and protein sequence searching are available in the Registry. Other CAS files provide detailed synthesis and reaction information. For ceramics, inorganic materials, and organometallic materials searching molecular formula, element counts and ring systems in the Registry file allow a high level of specificity as well as broad class identification of compounds and materials. The most complete versions of these files is available through STN International; however, the basic databases are available through all major database vendors.

5. *COMPENDEX (or EI or Engineering Index)*. Engineering Information Inc., EI Headquarters, 1 Castle Point Terrace, Hoboken, NJ 07030-5996. Tel: (+1) 201-216-8500. Fax: (+1) 201-216-8532. Toll free: (+1) 800-221-1044 US and Canada. Web: <http://www.ei.org/>. E-mail: [ei@ei.org](mailto:ei@ei.org). Indexes and abstracts information from the engineering and technological literature including over 2600 international journals, conference papers, and technical reports. Of special interest to materials engineers is the chemical, biomedical, and metals formation.

### ***Other Databases***

1. *Science Citation Index (part of Web of Science)*. ISI 3501, Market Street, Philadelphia, PA 19104. Phone: 800-336-4474 or 215-386-0100. Fax: 215-386-6362. Web: <http://www.isinet.com/isi/>. A citation index provides ready access to information on what papers are routinely being cited. They provide a method to broaden searches by finding out how seminal papers have been cited. Several database producers are now adding citation searching within their subject areas.

Science Citation Index provides access to current and retrospective bibliographic information, author abstracts, and cited references found in 3500 of the world's leading scholarly science and technical journals covering more than 150 disciplines. Its focus is on the most heavily used materials in all of science, thus allowing cross-disciplinary searching and retrieval of the most important references. (A related product Materials Science Citation Index may also be of interest as it provides a more focused group of journals.) Keyword and title word

searching is available, making this a useful but limited tool for subject searching. This database is best used in conjunction with more in-depth and formally indexed subject database.

2. *ProceedingsFirst*. OCLC Online Computer Library Center, Inc., 6565 Frantz Road, Dublin, Ohio 43017-3395. Phone: 1-800-848-5878. Fax: +1-614-764-6096. Web: <http://www.oclc.org>. E-mail: [support@oclc.org](mailto:support@oclc.org). Provides citations of every congress, symposium, conference, exposition, workshop, and meeting received at The British Library. Contains in each record a list of the papers presented at each conference.

3. *Derwent World Patents Index*. Derwent Information, 1725 Duke Street, Suite 250, Alexandria, VA 22314. Telephone: + 1-703-706-4220. Fax: +1-800-457-0850. Web: <http://www.derwent.com/index.html>. E-mail: [custserv@derwentus.com](mailto:custserv@derwentus.com). Derwent reviews and processes more than a million patents a year from over 40 international patent issuing authorities, as well as research papers and articles from more than 1200 other sources. The World Patents Index is one of the files they offer. Extensive chemical and engineering related indexing terminology as well as Markush structure searching is available in these resources.

### 1 INTRODUCTION AND SCOPE

It is the purpose of this chapter to aid engineers and materials scientists in locating reliable sources of high-quality materials property data. While sources in hardcopy form are referenced, the main focus is on electronic sources that provide well-documented searchable property data.

To identify useful sources of materials data, it is important to have clearly in mind at the outset (a) the intended use of data, (b) the type of data required, and (c) the quality of data required. These three factors are key in narrowing a search and improving its efficiency of a search for property data. Therefore, as an introduction to the identification of some specific potentially useful sources of materials data, we will discuss those three factors in some detail, and then describe the options available in types of data sources.

It is beyond the scope of this publication to attempt to provide a comprehensive list of all of the several thousand sources of materials data in various forms and formats. Readers interested in a more comprehensive list of sources and of more discussion of the technology of material property data technology and terminology are referred to Westbrook's extensive treatment of these subjects in

Refs. 1 and 2 and to *ASM International Directory of Material Property Databases*.<sup>3</sup>

## 2 INTENDED USES FOR DATA

Numeric material property data are typically needed for one of the following purposes by individuals performing the respective functions as part of their jobs:

- Modeling material or product performance
- Materials selection (finding candidate materials for specific applications)
- Analytical comparisons (narrowing the choices)
- Preliminary design (initially sizing the components)
- Final design (assuring performance; setting performance specifications)
- Material specification (defining specifications for purchase)
- Manufacturing (assuring processes to achieve desired product)
- Quality assurance (monitoring manufacturing quality)
- Maintenance (repairing deterioration/damage)
- Failure analysis (figuring out what went wrong)

It is useful to note some of the differing characteristics of data needed for these different functions.

### 2.1 Modeling Material and/or Product Performance

To an increasing extent, mathematic modeling is used to establish the first estimates of the required product performance and material behavior, and even in some cases the optimum manufacturing processes that should be used to achieve the desired performance. The processes and/or performance analyzed and represented may include any of the issues addressed in the following paragraphs, and so the nature of the types of data described under the various needs are the same as those needed for the modeling process itself.

### 2.2 Materials Selection

The needs of materials specialists and engineers looking for materials data to aid in the selection of a material for some specific application are likely to be influenced by whether they are (a) in the early stages of their process or (b) have already narrowed the options down to two or three candidates and are trying to make the final choice. The second situation is covered in Section 2.3, Analytical Comparisons.

If the materials engineers are in the early stages of finding candidate materials for the application, they are likely to be looking for a wide variety of properties for a number of candidate materials. More often, however, they may decide to focus on two or three key properties that most closely define the requirements for that application and search for all possible materials providing relatively favorable combinations of those key properties. In either case, they may not be as much concerned about the quality and statistical reliability of the data at this stage as much as the ability to find a wide variety of candidates and to make direct comparisons of the performance of those candidates.

In cases where there is interest in including relatively newly developed materials in the survey, it may be necessary to be satisfied with only a few representative test results or even educated “guesstimates” of how the new materials may be expected to perform. The engineers will need to be able to translate these few data into comparisons with the more established materials, but at this stage they are probably most concerned with not missing out on important new materials.

Thus, at this early stage of materials selection, the decision makers may be willing to accept data rather widely ranging in type and quality, with few restrictions on statistical reliability. They may even be satisfied with quite limited data to identify a candidate that may merit further evaluation.

### 2.3 Analytical Comparisons

If on the other hand, the task is to make a final decision on which of two or three candidate materials should be selected for design implementation (the process defined here as “analytical comparison”), the quality and reliability of the data become substantially more important, particularly with regard to the key performance requirements for the application. It will be important that all of those key properties, e.g., density, tensile yield strength, and plane-strain fracture toughness, are available for all of the candidate materials that may be the next cut in the list.

The search will also be for data sources where the background of the data are well defined in terms of the number of tests made, the number of different lots tested, and whether the numbers included in the data source are averages or the result of some statistical calculation such as that to define three  $\sigma$  limits, for example. It would not be appropriate at this stage to be uncertain whether the available data represent typical, average values or statistically minimum properties; it may not be important which they are, but the same quality and reliability must be available for all of the final candidates for a useful decision to be made.

In addition, the ability to make direct comparisons of properties generated by essentially the same, ideally standard, methods is very important. The decision maker will want to be able to determine if the properties reported were determined from the same or similar procedures and whether or not those procedures conformed to ASTM International, International Organization for Standardization (ISO),<sup>4</sup> or other applicable standard test methods.

One final requirement is added at this stage: The materials themselves for which the data are presented must all represent to the degree possible comparable stages of material production history. It would be unwise to base serious decisions on comparisons of data for a laboratory sample on one hand and a commercial size production lot on the other. Laboratory samples have a regrettable history of promising performance seldom replicated in production-size lots.

Thus, for analytical comparisons for final candidate material selection, specialists need databases for which a relatively complete background of metadata (i.e., data about the data) are included and readily accessible.

Incidentally, it is not unusual at this point in the total process to decide that more data are needed for a particular candidate than are available in any existing

database, and so a new series of tests are needed to increase confidence in the comparisons being made.

## 2.4 Preliminary Design

Once a decision is made on a candidate material (or sometimes two) for an application, the task of designing a real component out of that material begins. The requirement for statistical reliability steps up, and the importance of the availability of a data source that provides applicable metadata covering quality, reliability, and material history becomes even more important.

At this stage, the statistical reliability required includes not only a minimum value but one based upon a statistically significant sample size, ideally something comparable to the standards required in the establishment of MIL-HDBK-5's A or B values.<sup>5</sup> In MIL-HDBK-5 terminology, an A value is one that would be expected to be equaled or exceeded by 99% of the lots tested with 95% confidence; the B value provides for 90% of lots tested equaling or exceeding the value with 95% confidence. Furthermore, the MIL-HDBK-5 guidelines require that A and B values be based upon predefined sample sizes, representing a minimum number of lots (normally 100 or more) and compositions (normally at least 3) of a given alloy. The provision of such statistical levels needs to be a part of data sources used for design purposes, and the description of the statistical quality needs to be readily available in the data source.

For preliminary design, then, the data sources sought will include both statistically reliable data and well-defined metadata concerning the quality and reliability provided.

## 2.5 Final Design

Setting the final design parameters for any component or structure typically requires not only data of the highest level of statistical reliability but also, in many cases, data that have been sanctioned by some group of experts for use for the given purpose. It is also not unusual that at this stage the need is identified for additional test data generated under conditions as close as possible to the intended service conditions, conditions perhaps not available from any commercial database.

Databases providing the level of information required at this stage often contain what are characterized as "evaluated" or "certified" values. Evaluated data are those that, in addition to whatever analytical or statistical treatment they have been given, have been overviewed by an expert or group of experts who make a judgment as to whether or not the data adequately and completely represent the intended service conditions, and if necessary incorporate their own analysis into the final figures. This technique has been widely used in digesting and promulgating representative physical property data for many years; examples are the thermophysical property data provided by Thermophysical Properties Research Center (TPRC).<sup>6</sup>

Other databases may be said to provide "certified" data. In this case, the database or set of data going into a database have been evaluated by a group of experts and certified as the appropriate ones to be used for the design of a particular type of structure. Two examples of this are the aforementioned MIL-HDBK-5 values,<sup>5</sup> which are approved for aircraft design by the MIL-HDBK-5

Coordination Committee consisting of aerospace materials experts; and the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code,<sup>7</sup> with properties certified by materials experts in that field for the design of pressure vessels and companion equipment for high-temperature chemical processes.

As noted, it is often the case when designers reach this stage (if not the earlier preliminary design stage) that they find it necessary to conduct additional tests of some very specialized type to ensure adequate performance under the specific conditions the component or structure will see in service but for which reliable databases have not previously been identified or developed. The net result is the creation of new materials databases to meet highly specialized needs in a manner that provides the appropriate level of statistical confidence.

## 2.6 Material Specification

Material specifications typically include specific property values that must be equaled or exceeded in tests of those materials that are being bought and sold. The properties that one requires in this case may differ from those needed for other purposes in two respects. First and foremost, they must be properties that will ensure that the material has been given the desired mechanical and thermal processing to consistently achieve the desired performance. The second requirement is that, while in most cases there may be only one or a very few properties required (most often tensile properties), they are required at a very high level of precision and accuracy, similar to or better than that required for the MIL-HDBK-5 A properties defined earlier.

Examples are the material specifications required for the purchase of commercial aluminum alloy products.<sup>8</sup> These are usually only the chemical composition and the tensile properties. So while many of the other properties needed for design are not required as part of the purchase specification, those properties that are required are needed with very high reliability. In the case of aluminum alloys, the requirements for tensile strength, yield strength, and elongation are normally that 99% of lots produced must have properties that equal or exceed the published purchase specification values with 95% confidence, and they must have been defined from more than 100 different production lots from two or more producers.

In many cases, the databases needed to generate material specification properties are proprietary and are contained within individual companies or within the organizations that set industry specifications. However, the resultant statistically reliable specification properties are resident and more readily available in industry or ASTM material standards.<sup>4,8</sup>

## 2.7 Manufacturing

The properties required for manufacturing purposes may be the most difficult to find in commercially available databases because they typically involve the specialized treatments or processes utilized by specific producers or suppliers of the specific products in question. Sometimes these processes are proprietary and closely held for competitive advantage. An added complication is that once some semifabricated component (e.g., aircraft sheet) has been purchased, it will require forming to very tight tolerances or finishing at some relatively high temperature.

The fabricator may require data to enable the process to be carried through without otherwise damaging or changing the properties of the component, but may have difficulty representing the fabricating conditions in meaningful tests. That fabricator may well have to carry out its own tests and build the needed database to provide the desired assurance of quality, and to provide a source of information to which its own employees can refer to answer specific questions. Typically such databases never become commercially available, and new situations will require compiling new data sources.

Some processing data sources are available, of course. The Aluminum Association, Inc., for example, provides to all interested parties a data source defining standard solution heat treating, artificial aging, and annealing treatments for aluminum alloys that will assure the proper levels of properties will be obtained.<sup>8</sup> In some cases, ASTM and the American National Standards Institute (ANSI) material specifications will also contain such information.

## **2.8 Quality Assurance**

Quality assurance may be considered to be the flip side of material specifications, and so the types of data and the data sources themselves required for the two functions are essentially the same.

Purchasers of materials, for example, may chose to do their own testing of the materials once delivered to their facilities by materials producers. If so, they will use exactly the same tests and refer to exactly the same data sources to determine compliance. The one difference may be that such purchasers may chose to gradually accumulate the results of such tests and build their own databases for internal use, not only by their quality control experts, but also by their designers and materials experts who must establish safe levels of performance of the structures. These types of databases also tend to be proprietary, of course, and are seldom made available to the outside world, especially competitors.

## **2.9 Maintenance**

The principal value of material data in connection with maintenance concerns will likely be for reference purposes when problems show up with either deterioration of surface conditions or the suspicion of the development of fatigue cracks at local stress raisers.

In both cases, the important features of the types of data desired to address such issues are more likely to be those based upon individual exposures or prior service experience, and so the user may be more concerned about the degree of applicability than upon data quality and statistical reliability (though both features would be desired if available). Typically such data are hard to find in any event, and once again are more likely to be buried in proprietary files than in published databases.

In the case of engineers and technicians needing databases comprised of service experience, they may well be faced with building their own data sources based upon their organization's production and service experience than expecting to be able to locate applicable external sources.

## 2.10 Failure Analysis

The occurrence of unexpected failure of components in a structure usually calls for some follow-up study to determine the cause and possible ways to avoid further loss. In such cases it is inevitable that such failure analysis will involve both (a) a review of the old databases used to design the part and (b) a search for or the development of new data sources that may shed more light on the material's response to conditions that developed during the life of the structure that had not been anticipated beforehand.

The types of databases sought in this case will likely be those containing statistically reliable data, but recognizing the unexpected nature of some problems, an interest in a wider range of data sources and a willingness to consider a lower level of data quality may result. Databases for failure analysis studies may need to be wider in scope and to cover subjects such as corrosion that are not always easily treated by statistical means. In fact, sources covering failure experience may be the most valuable, though hardest to find because historically engineers and scientists do not publish much detail about their mistakes.

The net result is that when dealing with failure analysis, the search may be quite broad in terms of data quality, and the focus most likely will be more on applicability to the problem than on the quality and structure of the compilation. As in the case of maintenance engineers and technicians needing databases comprised of service experience, failure analysts may well be faced with building new data sources based upon their organization's production and service experience.

## 3 TYPES OF DATA

It is useful at this stage to note that there are several basic types of materials databases, i.e., databases containing significantly different types of information and, hence, different data formats. Note that this is different from the type of platform or presentation format (e.g., hardcopy, CD, online, etc.); these will be discussed in Section 6.

The two fundamental types of databases discussed here are *textual data* and *numeric data*. In fact, many databases represent a combination of both types, but there are some basic differences worth noting as in the next two paragraphs. The concept of metadata will also be described in more detail in this section.

### 3.1 Textual Data

The terminology *textual data* is generally applied to data entries that are purely alphabetic in nature with numbers used only as necessary to complete the thoughts. Textual databases are typically searched with alphabetical strings, e.g., by searching for all occurrences of a term such as *aluminum* or *metallurgy* or whatever subject is of interest.

The subjects of textual databases are predominantly bibliographies and abstracts of publications, but they may reflect other specific subjects such as textual descriptions of failures of components, for example. Bibliographic databases seldom reflect the final answers to whatever inquiry is in mind but rather references to sources where the answers may be found.

The majority of all databases in existence in any form (see Section 6) are textual in nature, even many of those purporting to be property databases. Searchers of such textual property databases are searching based upon strings of alphanumeric characters reflecting their interest, not on numeric values of the properties except as they are expressed as strings. This is quite different from the case for numeric property databases, as we shall see in the next section.

### 3.2 Numeric Databases

Databases classed as numeric (a) have data stored in them in numeric format and (b) are searched numerically. For example, numeric databases may be searched for all materials having a specific property equal to or greater than a certain value or within a certain specific range; this would not be possible in a textual database. To provide such searchability, almost all numeric databases are electronic in nature (see Section 4) though many hardcopy publications also contain extensive amounts of numeric data.

To accommodate numeric searching, the properties must be entered into a database digitally as numbers not simply as alphanumeric strings. And to be useful to material specialists and designers, they must have meaningful precision (i.e., numbers of significant figures) and units associated with each number. The numeric number of a property is of no value if it does not have the applicable unit(s) associated with it.

### 3.3 Metadata

The concept of metadata as “data about data” was introduced earlier, and it is appropriate at this stage to describe the concept and its importance in greater detail.<sup>9</sup> It is vital, especially for numeric databases and independent of their platform, to have ample background information on the numeric properties included in the database and closely associated with the individual properties.

Examples of metadata include:

- Original source of data (e.g., from tests at ABC laboratories)
- Test methods by which data were obtained (e.g., ASTM methods, size and type of specimen)
- Production history of the samples for which the data are applicable (e.g., annealed, heat treated, cold worked, special handling?)
- Exposure experienced by the samples tested, if any, prior to the test (e.g., held 1000 h at 500°F)
- Conditions under which the properties were determined (e.g., tested at 300°F, 50% humidity)
- Number of individual tests represented by and statistical precision of the values presented (e.g., individual test results; averages of  $x$  number of tests, statistical basis)
- Any subsequent evaluation or certification of the data by experts (e.g., ASME Boiler & Pressure Vessel Committee)

It should be clear that the value of information in any database, but especially in a numeric database, is greatly diminished by the absence of at least some and

potentially all of these types of metadata. For example, a listing of the properties of an alloy is of no value at all if it is not clear at what temperature they were determined. It should be clear that metadata are an integral part of every material property database. Similar properties of a material are of virtually no value if it is not clear how they were mechanically and thermally processed before they were tested.

#### 4 SUBJECTS OF DATA SOURCES

It is next useful to note some of the major categories of data available and illustrate the manner in which they are likely to be classified or structured. From this point on, the discussion will focus primarily upon numeric materials property data of interest to the engineer and scientist.

The total breadth of properties and characteristics may reasonably be illustrated by the following four categories:

- Fundamental (atomic level) properties
- Physical properties (atomic and macro/alloy levels)
- Mechanical properties (macro/alloy level)
- Application performance (macro/alloy or component levels)

To provide greater detail on the first three categories, it is helpful to utilize the taxonomy of materials information developed by Westbrook<sup>1</sup> and illustrated in Fig. 1. While the entire list of potential uses of data described above is not included, the taxonomy in Fig. 1 illustrates the variety of subject matter quite well.

The fourth major category identified above involves what is referred to as application performance but which in itself incorporates several individual areas:

- Fabrication characteristics (sometimes called the “ilities”)
  - (a) Fabricability (“workability”)
  - (b) Forming characteristics (“formability”)
  - (c) Joining characteristics (“joinability”)
  - (d) Finishing characteristics (“finishability”)
- Service experience
  - (a) Exposure conditions
  - (b) Service history
  - (c) Failures observed and their causes

It is not necessary to discuss these categories individually, simply to recognize that specific databases may well focus on only one or a few of these subjects and that rarely if ever would all subjects be included in any one database.

#### 5 DATA QUALITY AND RELIABILITY

It was noted in Section 2 that individuals doing preliminary material selection or screening may have different needs with regard to quality and reliability than those doing design functions. It is appropriate at this stage to review the major

**Fig. 1** Taxonomy of materials information. From *ASM Handbook, Vol. 20: Materials Selection and Design* (1997), ASM International, Materials Park, OH 44073-0002, fig. 1, page 491.

factors that go into judgments of data quality and reliability.<sup>10</sup> There are two parts to such a discussion: (1) the two major factors affecting the data themselves and (2) the degree to which those factors are reflected in database content.

The two factors affecting quality and reliability include (a) the manner in which the data were obtained and (b) the statistical reliability of the data presented.

First and foremost, the users of a database for whatever purpose will want to know that consistent standards were applied in assembling the data for that database, and that the properties of one material may reliably be compared with those for another. They would also prefer that those properties have been generated by well-known standard methods such as those prescribed by organizations such as ASTM and ISO.<sup>4</sup> They may also be quite interested in knowing

the specific source of the original data; realistically some laboratories [e.g., the National Institute of Standards and Technology (NIST)] have a more widely recognized reputation than others.

The second major factor affecting how the user applies information from a specific database is the statistical reliability of the values included therein. The user will be interested in which of the following categories best describes the values presented:

- Raw data (the results of individual tests)
- Average of multiple tests (how many tests represented?)
- Statistically analyzed (at what statistical definition and with what confidence?)
- Evaluated/certified (by whom? for what purpose?)

Of equal importance to the user of any database for whatever reason is the degree to which those factors affecting quality and reliability as noted above are presented in the database itself and, therefore, are fully understood by the user. In some instances there may be one or several screens of background information laying out the general guidelines upon which the database was generated. This is particularly effective if the entire database represents properties of a common lineage and character. On the other hand, if the user fails to consult this upfront information, some important delimiters may be missed and the data misinterpreted.

Another means of presenting the metadata concerning quality and reliability is within the database itself. This is especially true for such factors as time–temperature parameters that delimit the applicability of the data and units and other elements of information that may restrict its application (see Section 3.3).

It is also especially important in instances where the individual values may vary with respect to their statistical reliability. While the later case may seem unlikely, it is actually quite common, as when “design” data are presented: in such cases, the strength values are likely to be statistical minimum values while moduli of elasticity and physical properties are likely to be average values, and the difference should be made clear in the database.

## 6 PLATFORMS: TYPES OF DATA SOURCES

The last feature we will consider before identifying specific data sources is the variety of platforms available for databases today. While it is not necessary to discuss them in detail, it will be obvious that the following choices exist:

- Hardcopy (published books, monographs, etc.)
- Self-contained electronic (floppies, CDs, etc.)
- Internet sites (available online; perhaps downloadable)

The only amplification needed on these obvious options is that the last one, the Internet, has become an interesting resource from which to identify and locate specific sources of materials data, and that trend will likely continue to increase. Two large caveats go with the use of Internet sources however: (1) a

great deal of “junk” (i.e., unreliable, undocumented data) may be found on Internet web sites, and (2) even those containing more reliable data seldom meet all users needs with respect to covering the metadata. It is vital that the users themselves apply the guidelines listed earlier to judge the quality and reliability of sources located on the Internet.

## 7 SPECIFIC DATA SOURCES

It is beyond the scope of this chapter to provide an exhaustive list of data sources because there are thousands of them of varying presentation platforms, styles, and content. What we will do here is highlight a few of the potentially most useful sources, in the sense that their coverage is relatively broad and/or they represent good places to go to look for new and emerging sources of materials data.

The categories discussed below will include:

- ASM International, a technical society for materials engineers and specialists that produce and provide a wide range of materials databases in hardcopy and electronic form (see Section 7.1)
- STN International, a service of the American Chemical Society, also providing (for fee) access to a very wide range of numeric databases as well as a great many textual/bibliographic databases on materials-related subjects (see Section 7.2).
- The Internet, the most rapidly expanding source for materials data in a variety of forms (see Section 7.3).

For readers interested in more extensive listings, reference is made to the article “Sources of Materials Property Data and Information” by Jack Westbrook in Volume 20 of the *ASM Handbook*<sup>1</sup> and to the *ASM Directory of Databases*.<sup>3</sup>

### 7.1 ASM International

ASM International has emerged as one of the strongest providers of numeric materials data sources, and those sources are generally in at least two formats or platforms: hardcopy and disk, usually CD-ROM. As an example, one of the most extensive sources of high- and low-temperature data for aluminum alloys has recently been made available through a collaborative effort of ASM and the Aluminum Association, Inc., in both the book *Properties of Aluminum Alloys—Tensile, Creep, and Fatigue Data at High and Low Temperatures*<sup>11</sup> and a searchable CD of the same title. Other representative data sources from ASM International include:

- *ASM Handbook*,<sup>12</sup> in hardcopy and CD—20 volumes complete or available in a specific set covering material properties; the data sets are available for single workstations and also for local-area network (LAN) arrangements. Other CDs are available covering heat treatment, testing and analysis, and manufacturing processes.
- Alloy Finder CD—contains full alloy records from three ASM hardcopy reference standards: *Woldman’s Engineering Materials*,<sup>13</sup> the *ASM World-*

*wide Guide to Equivalent Irons and Steels*,<sup>14</sup> and the *ASM Worldwide Guide to Equivalent Nonferrous Metals and Alloys*.<sup>15</sup> The disk is searchable by composition as well as designation, so whether the user requires amplification of an alloy designation or to locate designations within specific composition ranges, the need is addressed.

- *Alloy Digest* on CD—Summaries of recently published data for new and emerging alloys are compiled periodically on disk as well as being made available in hardcopy. The advantages include early warning of new materials; the limitation is the inability to provide consistent formats or data scope because such are not available for relatively new materials. More than 4200 data sheets are now available.
- Binary Phase Diagrams on CD-ROM—The world's most extensive collection of binary phase diagrams numbering in excess of 4700 is available on CD, in addition to ASM's hardcopy publications such as *Handbook of Ternary Alloy Phase Diagrams* and the monograph series on specific alloy groupings.
- Failure Analysis on CD-ROM—One of the most extensive collections of data expressly developed for failure analysis is available on searchable CD-ROM as well as hardcopy.
- Materials databases on various classes of materials are available from ASM on disk in various formats including Mat.DB, MAPP, and Rover search software. The databases are organized and searchable by mechanical and physical property as well as alloy class: steel and stainless steel, aluminum, composites, copper, magnesium, plastics and polymers nylon, and titanium, plus a special disk covering corrosion data.

For more detailed information on ASM International's data sources, the reader is referred to its Internet web site: [www.asminternational.org](http://www.asminternational.org).

## 7.2 STN International

STN International is the online worldwide scientific and technical information network, and one of the most extensive sources of numeric materials property data.<sup>16</sup> Built and operated by the American Chemical Society at its Chemical Abstract Service site in Columbus, Ohio, STN International includes about 30 numeric databases, including many developed during the collaboration with the Materials Property Data Network.<sup>17–19</sup> Of great interest to materials data searchers, STN International has the most sophisticated numeric data search software available anywhere online. Thus the data sources may be searched numerically, i.e., using numeric values as ranges or with “greater or less than” types of operators, making it possible to search for alloys that meet required performance needs.

The disadvantages of using STN International to search for numeric data are twofold: (a) the search software is keyed to a command system best known to professional searchers, and engineers and scientists will need patience and some training to master the technique; and (b) use of the STN International system is billed via a time and content based cost accounting system, and so a private account is needed. Outright purchase of databases has not been a policy.

For those able to deal with those conditions, a number of valuable databases exists on STN International, including the following representative sources:

- ALFRAC—Aluminum Fracture Toughness Database (1968–1989 industry compilation)
- Aluminium—Aluminum Industry Abstracts (textual; 1868–present)
- ASMDATA—ASM Materials Databases online version
- BEILSTEIN—Beilstein Organic Compound Files (1779–1999)
- COPPERDATA—Copper and Copper Alloy Standards & Data
- DETHERM—Thermophysical Properties Database (1819–present)
- DIPPR—AIChE Design Institute Physical Property Data File (1982–present)
- GMELIN—GMELIN Handbook of Inorganic Chemistry (1817–present)
- ICSD—Inorganic Crystal Structure Database (1912–present)
- NUMERIGUIDE—Property Hierarchy and Directory for Numeric Files
- MDF—Metals Datafile (1982–1993)
- PIRA—PIRA and PAPERBASE Database (1975–present)
- PLASPEC—Plastics Material Selection Database
- RAPRA—Rubber, Plastics, Adhesives, and Polymer Composites (1972–present)

For more information on STN International, readers are referred to the website [www.cas.org](http://www.cas.org).

### 7.3 Internet

As indicated earlier, there are many web sites on the Internet with materials information content. The challenge is to determine which have useful, reliable, and relatively easily accessible data. In the interests of readers, we will focus on guidance on these latter points developed by Fran Cverna, Director of Electronic and Reference Data Sources at ASM International, who recently produced and presented a survey of the scope and quality of materials data content found on Internet web sites.<sup>20</sup>

Among the most useful web sites of the several hundred screened by Cverna and her ASM resources are the following:

|                                                                                                      |                                                        |
|------------------------------------------------------------------------------------------------------|--------------------------------------------------------|
| <a href="http://www.about.com">www.about.com</a>                                                     | Internet search engine—search Materials and Properties |
| <a href="http://www.nist.gov/publicaffairs/database.htm">www.nist.gov/publicaffairs/database.htm</a> | NIST—standard reference database                       |
| <a href="http://www.ecn.purdue.edu/MPHO">www.ecn.purdue.edu/MPHO</a>                                 | TPRL—thermophysical properties data                    |
| <a href="http://id.inel.gov/shds">id.inel.gov/shds</a>                                               | U.S. government—solvent database                       |
| <a href="http://www.campusplastics.com">www.campusplastics.com</a>                                   | Campus consortium—plastics database                    |

|                                                                                          |                                                              |
|------------------------------------------------------------------------------------------|--------------------------------------------------------------|
| <a href="http://www.copper.org">www.copper.org</a>                                       | Copper Development Association—copper alloys database        |
| <a href="http://www.brushwellman.com/homepage.htm">www.brushwellman.com/homepage.htm</a> | Brush Wellman—supplier materials database                    |
| <a href="http://www.timet.com/overviewframe.html">www.timet.com/overviewframe.html</a>   | Timet—supplier materials database                            |
| <a href="http://www.specialmetals.com">www.specialmetals.com</a>                         | Special Metals—supplier materials database                   |
| <a href="http://www.cartech.com">www.cartech.com</a>                                     | Cartech—supplier materials database (compositions)           |
| <a href="http://www.macsteel.com/mdb">www.macsteel.com/mdb</a>                           | McSteel supplier materials database (limited)                |
| <a href="http://www.aluminum.org">www.aluminum.org</a>                                   | Aluminum Association applications—publications' limited data |

Of the sources above, two merit special mention, those being the Internet search engine site [www.about.com](http://www.about.com) and the National Institute for Science and Technology [(NIST) databases site, a part of the public affairs menu].

The [about.com](http://about.com) site provides an excellent means of locating materials data sites and provides a subcategory called “Materials Properties and Data” if you search for such information. Thirty-two sites are identified, some of which overlap the ASM survey, but others are unique to that site in my experience. Many included in the ASM survey are not included here, so the two are supplementary in scope. Among the specific types of information accessible via [about.com](http://about.com) are:

- Coefficient of thermal expansion
- Electrical conductivity
- Electrical resistivity
- Hardness conversion charts
- Metal temperature by color
- Metal weight calculator
- Periodic table of elements
- Specific gravity of metals
- Surface roughness comparison charts
- Thermal properties
- Wire gauge conversion tables
- Utilities to simplify tasks such as conversion charts for units, currency conversion, glossaries, acronym definitions, etc.

In addition there are links from [about.com](http://about.com) to many other materials sites, including one called [aluminum.com](http://aluminum.com) that also provides materials data for a variety of metals, but often without adequate citation and metadata.

The NIST database site provides direct online access to the highest quality, carefully evaluated numeric data from the following databases:

- Standard Reference Data—reliable scientific and technical data extracted from the world's literature, assessed for reliability and critically evaluated
- Ceramics WebBook—evaluated data and access to data centers as well as tools and resources
- Chemistry WebBook—chemical and physical property data for specific compounds
- Fundamental Physical Constants—internationally recommended values of a wide range of often used physical constants
- Thermophysical Properties of Gases for the Semiconductor Industry

To summarize the Internet discussion, there are many sources of numeric materials data available from Internet sites. It remains for the potential users of the data, however, to approach each site with caution, look for the pedigree of the data in terms of quality and reliability, and to make certain that the source used meets the requirement of the intended use.

### Acknowledgments

The contributions of Jack Westbrook (Brookline Technologies) and Fran Cverna (ASM International) are acknowledged.

Previous chapters have described the sources and usage of materials data in product manufacturing organizations. This chapter discusses the process of managing materials data. After examining its history, discussions will be provided on the design and implementation of materials data management systems, the design and creation of the underlying database(s), and the evolution and use of standards for materials data reporting and exchange. A brief summary of commercially available database management systems is provided. We will begin by establishing the premise that the ability to manage the vast amount of materials information used in manufacturing organizations is perceived as a tremendous tool for increasing efficiency and profitability.

Materials data is used to support many different functions in a manufacturing organization from the initial phases of design to the disposal requirements at the end of a products' life cycle. The most critical of these functions is the process of analysis, used to predict the product's performance in its end-use environment. The completeness of the required data sets is crucial to most forms of mathematical analysis required for engineering simulation. The pedigree or background data for the tested material property data, as well as the specific properties required for the analysis must be readily available to the analyst. These properties are either acquired from established sources or the result of rigorous testing or a combination of the two. It has been estimated that the cost

of testing for a complete set of materials properties required by a designer for a new application can be in excess of \$1 million with an acquisition time of greater than 5 years.<sup>1</sup> Additionally, it is estimated that engineers spend over half their time acquiring and verifying the validity of this data. Effective management of this data is paramount for organizations having functions that are materials data intensive. It reduces the cost of materials data acquisition, improves the usability and reusability of acquired data, and increases the efficiency of the engineering organization.

Historically, the confidence in a new product design relied on large safety margins and field service experience. The introduction of computerized design and analysis systems offered the promise of selecting the right material for an optimized design early in the product development cycle. This requires that consistent and high-quality materials information be used throughout the design to manufacturing process. In addition to the resulting cost reductions, the benefits of effective data management are realized in terms of higher quality, decreased warranty costs, shorter product development cycles, and traceable and auditable systems.<sup>2</sup>

So what does “materials data management” mean to an organization? It means:

- Making the materials properties acquired by an organization available to all functions requiring that data within the organization in a consistent and timely manner from an official, centralized source
- Providing a means of controlling the sources of materials properties used for a given function
- Controlling access to specialized and proprietary information
- Providing the available materials properties in a format that optimizes its usability and reusability

## 1 HISTORY OF MATERIALS DATA MANAGEMENT

In many organizations, the engineer responsible for a specific analysis maintains the information he requires. It is often found in old notebooks, jotted on scratch pads, in textbooks, and other references known only to him. This data provides little, if any, traceability and limited pedigree information. The values are often just simply those that have “always been used.” If the engineer leaves the organization, the search for the required data begins again. Often the data is not accessible to other individuals within the same company, and the acquisition process is duplicated, sometimes resulting in the use of different values for identical properties, producing inconsistencies in analysis of the same system or structure. It has been estimated that 50% of an engineer’s time is spent searching for and verifying materials property data.

Organizations for whom traceability is important often require “certified” data, which has been evaluated by experts and approved for a specific application. These organizations have long recognized the value of the materials data they use. Many organize the data into official handbooks that are distributed throughout the organization, fulfilling the requirement for controlling the data used in their analysis processes. However, the process of creating the handbooks

is time-consuming and costly. Rocketdyne Division of Boeing North America documented the process for adding data from a vendor for a new material into its handbook<sup>3</sup> in the following manner:

1. Test data obtained from vendor was typed into a curve-fitting program.
2. A best-fit curve was constructed based on the test data.
3. Archived data and data from other sources for the same material and test condition were retrieved to compare with the newly constructed curve.
4. If a difference existed between the new data and historical data for similar materials, the difference was reconciled in one way or another, and the new data was finalized.
5. A written report was generated for distribution to those who immediately needed the data.
6. The report was archived in the files.
7. The newly constructed curve would eventually be entered in the handbook.

Since the hardcopy manual was difficult to update, this process may have taken up to a year. Rocketdyne's hardcopy materials properties manual consisted of four volumes with over 1500 pages and 5000 curves. Revisions to this manual involved a major effort in terms of time, as well as paper.

As usage of computers became more widely available, companies began to realize the potential for tremendous cost savings through the optimization of their processes. They envisioned the capability for systems that would allow them to go beyond mere data storage within their organizations. The specialized use of computers in storing materials data for access by designers and analysts companywide provided new capabilities to search for and compare materials based upon specified properties and allowed designers to consider new materials options early in the design phase of a new product cycle. The possibilities for shortening the design cycle, making products of higher quality, improving the consistency of manufactured parts became a reality. Most of these improvements were driven by the need to improve profitability, others by the need to provide audit trails as required for ISO 9000 compliance. Response to these new requirements has led to the development of numerous "materials databases" in the past decade, either as commercially available products or in-house developments.

The introduction of product data management (PDM) systems to the marketplace provided additional tools for the integration of product data throughout an organization. While slow to catch on, by 1999 the estimated market size for PDM systems reached \$1.6 billion. Its growth was driven by an increasing awareness of the value of these systems in improving workflow, configuration management, document and information integrity, and communication throughout the enterprise.<sup>4</sup> Various specialized functions, including materials data management systems, are now being linked with PDM systems. For the manufacturing community, PDM is a natural complement to computer-aided engineering (CAE), by providing a repository for data that is accessed by CAE. The integration of CAE and PDM enables the access, verification, and control for

CAE input and output data.<sup>5</sup> “Simulation data management” is vital to the integration of CAE into the product development process. The benefits are analogous to those of materials data management systems and include:

- Improved access to authorized data sources
- Higher throughput for analysts and designers, resulting in faster and more reliable engineering decisions
- Fewer simulation errors, increased repeatability of simulation methods, with full traceability
- Enhanced collaboration between design and simulation, within the enterprise and throughout the supply chain

The Internet, or World Wide Web, has been credited with the substantially increased market for PDM-type systems. Being universal, inexpensive, accessible, and hardware-independent, web-enabled PDM formed a prototype for web-enabled materials data management systems. Even in organizations where the databases are not fully integrated, and legacy systems remain, web enablement allows the data from multiple sources to be displayed on the screen at the same time. This includes not only data from the PDM system but from the shop floor, parts management systems, purchasing, finance, shipping, and legacy systems as well. Once accessed, a web interface, with the look and feel of standard reporting mechanisms, can be used to generate reports by simply printing the screen. Most companies find that establishing a workable web browser interface as a front end to their PDM system is quite simple, requiring minimal programming expertise and technical support.<sup>6</sup>

While the Internet provides access from or to vastly different sources, the Intranet has enabled organizations to distribute materials information from a centralized location to all its satellite offices and divisions. This burgeoning expertise has facilitated the distributed “build-design” teams in many global enterprises that support the “design anywhere, build anywhere” business model.

As use and acceptance of these systems expand, additional applications have surfaced in the area of business-to-business collaboration. The power of the Internet allows companies to readily transact with each other and access each other’s information, making collaboration a reality. The first wave of Internet collaboration was in the supply chain, as companies worked with customers, suppliers, and intermediaries to manage inventories. By simplifying transactions and sharing information, companies continue to drive down costs, cut cycle times, and reduce inventories. The cutting edge of supply-chain collaboration is moving upstream from there. Intermediaries and suppliers are now doing collaborative planning and forecasting, creating a shared vision of what customers will eventually buy, so that the right product can be in the right place at the right time. Companies are also collaborating on product development. Instead of a system maker and a component supplier developing their products separately and then trying to make them fit, they use a shared design database to develop everything together from the outset. In some industries, competitors are standardizing on common parts and practices by sharing information over the Internet. Companies must be prepared to work with others—not out of a sense of

altruism, but for shared benefit.<sup>7</sup> Today, an array of “off-the-shelf” systems and custom implementations are available, making collaborative PDM tools convenient and economical for even small and medium-size companies.

## 2 IMPLEMENTING A MATERIALS DATA MANAGEMENT SYSTEM

Based on the previous discussion, it is apparent that the primary drivers for materials data management in today’s industries are the requirements to:

- Reduce the time to manufacture and the associated need for quick access to approved data.
- Disseminate or exchange data between different functions or organizations.
- Increase product quality and consistency resulting in lower warranty costs.
- Increase profitability by decreasing design, manufacturing, and testing costs.
- Improve traceability of data pedigree to substantiate product warranty claims.

Therefore, a materials data management system must be more than just a computerized version of a set of handbooks.<sup>8</sup> It must serve the material information requirements of the entire product life cycle. These include:

- *Conceptual design*, where materials information is required to screen candidate materials based on functional performance requirements and prior experience with candidate materials used in similar products.
- *Design*, where materials information is needed for specific (stock) materials, their grades and finishes, standard components and/or joining materials as specified in the engineering bill of materials. At this stage, specific material objects are designed and analyzed for end-use environments including manufacturing, assembly, service, maintenance, and disposal.
- *Manufacturing*, where materials information is needed for specific material object manufacturing processes, tooling, assembly fixtures, joining materials, dunnage, and in-process materials consumed during manufacture.
- *Operation*, where materials information is needed for in-service operation, including data for health monitoring, maintenance, repair, and other material-specific operating information provided by the manufacturer to the end-user.
- *Disposal*, where materials information on composition, procedures for recycling, and other environmental impact data are required at the end of the product’s service life.<sup>9</sup>

The success of a materials data management system lies in appreciating that the end users at each step of the product life cycle must access, retrieve, and manipulate approved materials data, and that the system structure, its user in-

terface, and its data content must be designed to provide for this wide range of usage at the outset. A well-designed and integrated materials data management system should provide efficient archiving and distribution of knowledge, eliminating duplicate materials testing, and optimizing the number of specified materials.<sup>10</sup>

Most current configurations of materials data management systems use client-server technology, incorporating a centralized database management system (DBMS), software applications that enhance the DBMS, and web access. As discussed earlier, the flow of data throughout the organization, exported in a usable format to each function may be enhanced by PDM configurations that interact with the materials data management system. Then the materials data becomes integrated throughout the organization. Otherwise, web enablement can provide easy access to the materials data management system by simple entry of a URL in a web browser window. The web-enabled materials data management system is the focus of the following discussions.

## **2.1 Planning**

A successful implementation requires full management commitment and careful planning, which includes the following elements:

- Clearly identifying the vision for a successful implementation, stated in terms of the company's business objectives. The vision statement is used to guide decisions for purchases and implementation and to define the metrics for success.
- Creating a project plan, resource allocation plan, and time allocation plan.
- Risk analysis and mitigation throughout all phases of the implementation.
- Planning and managing deployment and closure of each project and sub-project.

## **2.2 Implementation**

Implementation of a materials data management system is a customization of standard software development practices. The four phases in implementing a new software solution include analysis, design, implementation, and testing. The following sections provide information regarding the application of this process to the design of a materials data management system within a manufacturing organization. Implementation and testing, therefore, is followed by deployment of the software throughout the organization and system support.

### **Analysis**

The initial discovery phase provides the backbone for the entire implementation. Its goal is to understand the organizations' compelling needs and/or primary business drivers for implementation of materials data management, how it should function within the organization, and how the system should be deployed. Statements similar to the following represent typical business drivers:

- To reduce cost and process cycle time by a factor of 10
- To improve communication, integration, and flexibility

- To promote innovation and understanding of the use of new materials
- To improve productivity by running all operations from a single materials database
- To eliminate redundant materials testing by making data available to all analysis functions

This initial phase must first define and document the company's product development process and how materials data is currently used in that process. The use of detailed process charts for the mechanical design and analysis of the product can clearly identify the data flow requirements and allow for standardized methodologies.<sup>11</sup> All end users of the system and/or end-use applications with which the system must be integrated should be identified during this process. This may include the following materials-related functions:

- Product design
- Engineering analysis
- Materials engineering
- Manufacturing specification
- Materials ordering or bill of materials
- Other applications, such as PDM or collaborative PDM systems
- Functions at satellite offices

For each function, the following should be identified:

- The current data sources
- The types of data to be stored in the database
- How the data is retrieved and viewed
- The form the data must be in to be read by the individual applications
- How data it is to be reported or extracted from an application
- What standards and terminology must be utilized by the system
- Security or controlled access requirements
- Versioning control requirements

This preliminary requirements gathering provides an understanding of what schemas, databases, user interface requirements, queries, and other customizations may be required within the end user's environment. It also provides an indication of the internal and external resource requirements. The project may be further promoted by assessing, near term and long term, the cost of inaction.

***Deliverables:*** Preliminary findings document, vision statement, and the data flow diagram.

## **Design**

The system design phase must produce a detailed set of requirements for the system. Software requirements include the definitions of the user interface software, the DBMS, and any software required for versioning or controlled access

to the data. Hardware requirements should include preferred platforms for both client and server. From this, an initial materials information solution can be proposed and a return on investment (ROI) analysis provided.

Selecting a DBMS requires understanding your organizational requirements. While databases are traditionally designed to simplify the development of data-intensive applications, a carefully selected database management system can eliminate development altogether, by providing enough functionality that the end user can use the tools immediately to enter, examine, and process application data.<sup>12</sup> Traditional database requirements include:

- The ability to store a large volume of structured data
- Capability to retrieve data from storage via a simple query mechanism
- Distributed capability, allowing data storage on more than one location or machine
- An applications package, providing easy data modeling capability
- A crash recovery system, providing the ability to bring the database back to a consistent state automatically
- Data independence, allowing data changes without modifying existing application programs
- Reasonable performance requirements

Additionally, the DBMS used to store materials property data must have the capability to store and handle complex data types, including numerical values with units, footnotes, and numerical precision, graphical data, images, and documents.

The user interface software for a web-enabled materials data management system must typically provide the following capabilities, most of which will be identified in the discovery phase:

- Graphical displays for comparison of materials properties
- Search capabilities based on product names (character strings) or properties (numerical values)
- Interaction with data pre- and postprocessing applications, such as Excel or other proprietary software
- Ability to add to or delete data from the database
- Ability to extract or translate required data sets to identified applications, in required formats
- Ability to utilize existing standards for data modeling
- Ability to convert units between standardized unit systems, ensuring consistency in an analysis and compatibility with analysis or postprocessing software
- Customizability of the user interface, using common web interface methods and technology such as HTML and/or Java programming.<sup>13</sup>
- Versioning control or provision for a formal update process to ensure that a user can verify use of the most current data

- Secured or controlled access to subsets of stored data. Compilations of engineering knowledge, such as proprietary materials property data, represent a substantial investment for manufacturing companies, access to which must be carefully controlled. This is particularly challenging in global markets, where manufacturers may be partners on one project and competitors in another.<sup>13</sup> When dealing with the Internet or Intranet and PDM, both PDM security access and transmission security must be implemented. Outside a company's firewalls, transmissions can be secured by encrypting files in the vault prior to transmission. Within companies, usage can be secured using standard secured access processes.<sup>4</sup>
- Integration with other systems via PDM, application programmatic interface (API) or integrated client technology.

***Deliverable:*** Preliminary statement of requirements.

### Implementation

The implementation process is generally scheduled over a period of time, phasing in the database building process with implementation by the various functions requiring access to the data. This process can be facilitated logically by the use of the data flow diagram constructed in the initial design phase. It is often helpful to identify low-risk, high-return pilot implementation opportunities. The tasks for this phase include:

- Definition of implementation deliverables and milestones
- Identification of process redesign necessary prior to deployment
- Development of a timeline to achieve a total implementation (the implementation plan), including both pilot and fan-out
- Need for documentation and training
- Development of an executive summary based on results for reference by management
- Estimates of the return on investment (ROI), based on the implementation plan

***Deliverables:*** ROI Projections, requirements document (user and high-level technical requirements).

### Testing

This phase includes the installation of hardware and software for a specified portion of the organization or a specific function. To provide for a thorough evaluation of the software, a prototype database must be designed, built, and installed. The user interface must be designed or customized, and training materials created. Extensive testing must be performed on this initial concept of the solution. Usage, performance, support requirements, user issues, and data issues should be documented. From this, modifications to the software will be identified and implemented. Resource requirements can be refined, and the details for fan-out can be specified and adjustments made as required. ROI projections can be revised accordingly.

Success at this stage can be measured by the ability of a team to quickly integrate the system into their day-to-day activities, documented time savings in retrieving data, exporting data to specified applications, comparing materials, and meeting reporting requirements.

***Deliverables:*** Design document, and a functional application to be scaled into a production application in the next phase.

### 2.3 Deployment and Support

At this phase, upgraded software is installed at the pilot installation site, verified, and evaluated. Customization of the user interface is refined. Training should be extended to include the remaining user and administrative community. Database production procedures should be developed and implemented. Database building is expected to continue, but the schema design should be finalized based on user experience.

If the upgraded implementation is satisfactory, fan-out is continued based on the adjusted implementation plans. In the case of web-enabled access, the application software can be installed on the designated servers and accessed from client machines. The web browser interface should be refined based up the most up-to-date customized version of the software application. The requirements for ongoing support should be defined.

Success is measured by centralized access to approved materials data for all specified engineering and manufacturing functions. The majority of end users should feel comfortable with the revised materials processes. Materials-related activities should exhibit increased efficiency.

***Deliverables:*** Customer training/administration/user manual(s) and production application with complete production data integration.

## 3 CREATING THE DATABASE

The following is an overview of the process used to design and create a materials database that best meets the specifications of the end users. It is not the intent of this section to provide an exhaustive study of database design and implementation but only a general understanding of the scope of the tasks for creating a database useful to a manufacturing organization. There are many excellent resources available on this topic, from extremely technical to hands-on resource guides. In most instances, the reference guides provided with DBMS software adequately describe the technical details of database design required to physically create a database for use with that application.

The success of any project, especially that of creating a materials database from numerous sources of data, requires careful planning and the commitment and organization provided by a project team. The approach outlined in this section requires defining the database in the context of the individual end-use applications to assure that all end-users have as complete a data set as possible. The requirements for each end-use application may then be merged to create one database. After the database is compiled, the interface can be customized to optimize use of the database by the various end users.

### 3.1 Defining the Project Team

In creating the project team for designing and creating the databases, the following functions are suggested. It is highly recommended to have one individual, generally the project leader, who provides the focal point for all communications involved in the database design and building process.

The *project leader* must champion the cause, organize the project, and coordinate the effort. This person sets the milestones, establishes acceptance criteria, periodically reviews the project, and puts in place the approval procedures.

The *end user* defines the end use of the database, which must supply all necessary information in a usable form. Therefore, the end users should be involved in every level of database design and development. Their input determines what materials and what information for each material are stored in the database, how the data is stored, how the data is retrieved, how the user interface is customized, how the data is exported, and what unit conversions are required. Note that a database may be developed primarily for the organization and storage of data. In this case, the end user is often also the data provider.

The *data provider* is a focal point for all data sources. This person is responsible for gathering the information from all data sources required to meet the needs of the end users. He compiles the data, identifies and documents the storage media and format, and organizes it for entry into the database. Input from the data provider helps to determine the most efficient methods for data entry.

The *programmer* is responsible for translating electronically formatted data into formatted files for loading data into the database. This person is also valued for his expertise if data reduction or manipulation is required prior to data entry.

The *database builder* creates the database using the tools provided by the DBMS application. The database builder compiles all the information provided by the end users, creates the schema design, creates or compiles the data loading files and/or techniques, initializes and loads the database, creates all required auxiliary files, and corrects errors discovered during the quality assurance process.

### 3.2 Defining the End User Data Requirements

While efficient data storage may seem to be the purpose of a database system, the utility of the database is severely limited if it is not designed to meet the needs of the end use application(s). Therefore, a clear understanding of both the short-term and long-term end user applications is required.

*For each application identified in the initial planning phase, specify the following materials data storage requirements should be specified:*

- What materials are to be included?
- What information is applied globally to all end users?
- What pedigree information is required for each material?
- What properties are required for each material to optimize use of the database by the end user?
- What information is best provided as footnotes or metadata? (i.e., it is too sparse to require an attribute or too irregular to categorize)

- What are the user access privileges? Is some data restricted?
- What assumptions must be avoided?
- How often must this data be updated?

### 3.3 Defining the Functional Requirements

Most of the functional requirements are a result of or defined by the end user application. When defining the functional requirements, try to anticipate future applications for the database. Typically, the following questions should be answered:

- What types of queries (groupings of subsets of data) or data searches, list them if possible, will be performed on the database?
- What information is required to adequately identify the material records returned by the query or search?
- Will curve, table, or matrix data need to be represented?
- Will data be mathematically manipulated, required by pre- or postprocessing, and what is the required accuracy?
- What information is routinely accessed?
- Will the data be exchanged with or exported to other applications?
- What will be the acceptance criteria? Define the individuals responsible for approval.

### 3.4 Designing the Database

Materials data management systems typically have similar interface requirements, but the underlying database will be one of three common structures: relational, hierarchical, or a hybrid of the two. The following discussion relates to the process of creating a hybrid hierarchical-relational database. Comments are provided for their adaptation to relational databases.

Before beginning the database design, it must be determined whether to store the data in one database to be accessed by all end users or to divide the data into separate databases. This relates to decisions regarding the requirement for a distributed database system. Note that data can be stored in one database and then subdivided into separated databases for the individual end use applications. This often makes the process of updating the databases simpler. Some of the questions to be answered include:

- Will the total volume of data be unwieldy? Smaller databases are always faster and easier to update.
- Are the end uses similar or radically different? Is one or many databases expected by the end user?
- Will the data sources be updated on disparate schedules (i.e., archival data vs. ongoing test data)?
- How well do the categories of attributes that define the materials from different end users overlap? Can multiple databases use the same schema?

- Are the materials properties tested to similar standards?
- Does the database size pose a problem for any of the end users based on performance requirements?

Having developed an understanding of the end users and how they intend to use the database and data, it can then be determined which elements are to be stored in the database (or each database). More data may be available than is required to meet the end user requirements. Data that is not specifically required by any of the end users should be evaluated for its potential utility before being added to the database. Often it is desirable to keep all available data in one place as an official repository.

Once all data elements are listed, the relationship between the elements is established. This information is used for the development of the database schema, which defines how the data is structured within the database. The following information, preferably compiled in sequence, is required for *each application*.

**1. *The Data Elements (Attributes)*.** Database attributes are a numerical, textual, or graphical representation of the data. Textual attributes are useful for storing documents related to materials, tests, test data, property data, engineering specifications, revision histories, etc. Images are often included to demonstrate test layouts, engineering drawings, photomicrographs of test results, photos of specimens or products, etc.

All attributes that are required to provide the end user with the information necessary to qualify material property values and to provide the property values themselves for the materials in the database must be identified. These attributes should serve one of the following functions:

- To characterize the material to the level required by the user. The American Society for Testing and Materials (ASTM) and other organizations provide standards for accurately characterizing materials.
- To identify the source of the data. Data provided by different organizations may include the name of the organization, address, phone, test employee identifiers, etc. Validated data may require different parameters than test qualification. In-house or in-process test data may include the test group and employee identification or similar parameters for tracking purposes.
- To identify test parameters, conditions, methods, and the details of the test specimen. ASTM provides standards for identifying and qualifying test methods.
- To identify the property values to be stored in the database for the materials. This includes single-point scalar and test values, curves (arrays), images, and documents.

**2. *The Attribute Definitions*.** The attribute names and definitions provide a dictionary relating the attributes to terminology easily understood by the end user. These names and definitions are used in the schema that defines the database structure, to create customization files, and in quality control procedures.

Relational databases typically use field specifications to define attributes. Field specifications are composed of five types of elements: general elements, physical elements, logical elements, and specification information. Field-level and data-level integrity are established using thorough definition of the field specifications for each attribute.

Attribute definitions should include, as a minimum, the following information for a materials database:

- *Attribute Type* (Physical Element). The attribute type determines the form by which data can be searched and how it can be manipulated. This may include character strings, integers, real numbers, curves, matrices, text files, images, etc.
- *Units* (Logical Element). A consistent unit system must be provided for the entire database. The units must be consistent for each instance of an attribute in the database. Unit conversions may be required to provide the end user with useful information in the units system required by his application.
- *Description* (General Element). The attribute should provide a description of the attribute name in terms the end user understands. This label is typically used in displaying and searching data.
- *Numerical Precision* (Physical Element). The attribute precision provides the number of significant digits to which data is to be stored in the database and number of significant digits to which data will be displayed. This applies to all real, curve, and matrix values. American Iron and Steel Institute (AISI) provides standards for precision of computed values.
- *Constraints for Allowable Values* (Logical Element). Determine and record data constraints to identify out-of-range data during the data entry process. Also determine existence constraints when the data must be supplied for a material or property in order for it to be a valid entry in the database. This information can be used for data translation, database building, and quality assurance.
- *Attributes for Thesaurus or On-Line Help* (General Element). Identify information relating to the attributes that should be provided as end user documentation.
- *Test Specifications* (General Element). Identify and record test specifications, conditions, or identification that applies to all instances of property attributes.
- *Quality Indicators* (Specification Information). Quality (statistical) indicators or qualifiers required to qualify the data for the end user should be provided for property data. For example, the National Institute of Standards and Technology (NIST) provides the following guidelines for use of its on-line Ceramics WebBook, a collection of property values derived from surveys of published data<sup>14</sup>:

Certified (standard reference values)

Validated (confirmed via correlations and models)

Evaluated (basic acceptance criteria satisfied)

Commercial (manufacturer's data)

Typical (derived from surveys from values for nominally similar materials)

Research (preliminary values; work in progress)

Unevaluated (all other data)

3. *The Attribute Groups.* Having identified the attributes to be included in the database, they are now grouped by common characteristics in the context of the end user. Typical groups of attributes are specimen identification, material composition, specimen condition, specimen preparation, test conditions, mechanical properties, electrical properties, physical properties, etc. These groups of attributes are referred to as relations or tables.

It is important to verify that all the attributes belong to an appropriate relation. If the database has more than one end use application, the requirements for each are integrated, while avoiding redundancy. Additional tables may be added to improve data normalization.

Purely relational databases require the addition of key attributes to each relation that uniquely define each row in the table. These keys are used to link the tables for the purposes of uniquely identifying a material in the database and querying information from the database. Hierarchical databases use a combined set of attribute values for a material stored in the database to uniquely define the material record.

4. *The Relation Names for Attribute Groups.* A name must be assigned to each group of attributes using a term that best characterizes the grouping. Relation names are very important in relational databases, as they are specified in the SQL queries used to retrieve data from the database. Therefore, they must be unique, descriptive, and unambiguous. Relation names are not as important in hierarchical databases because they are not typically used in querying, but it is good practice to maintain their uniqueness.

5. *The Relationship between Relations.* For databases with a hierarchical structure, the relationship between the groups of attributes defines the hierarchy (parent-child relationships) of the database, dictating the structure for the schema design. This hierarchy provides the path to the property data. The relations should be separated into two groups: those that identify characteristics for the materials and those that specify properties of the materials. The tables storing defining characteristics are typically ordered according to the level of material differentiation the data provides, from the least differentiation (i.e., material, test type, component) to the highest (i.e., test conditions, source data). The relations that contain attributes that define the actual property data are grouped into tables by type and are typically on the same level at the bottom of the hierarchy.

For relational databases, the relationship between the groups of attributes establishes the connection between relations that are logically related to each other in some form or manner.<sup>15</sup> These relations are used to refine table structures, minimize redundant data, allow data to be drawn together simultaneously, and provide for relationship-level integrity.

Hierarchical database relations generally have one-to-many relationships progressing down the levels of the schema. Relational databases usually have one or more of three types of relationships: one-to-one, one-to-many, and many-to-many.

**6. *The Schema.*** The information gathered in the previous steps is organized to create the schema for a hierarchical database or can be used to establish the relationships and create the field specifications for a relational database. This step must be performed before the actual data is loaded into the database.

### **3.5 Developing a Prototype Database**

All the accumulated knowledge, expertise, and information are now used to create a prototype database. This database aids in clarifying goals, identifying problems in the design or content, identifying additional resources or information required by the end user, establishing the end users' expectations, and refining the project.

The prototype database should be built from a small subset of the data to be stored in the database. This subset should include at least one example of each of the attributes defined in the schema. If data is obtained from several different sources or serves different end users, the prototype database should contain at least one complete data set from each source and for each end user. If curves or graphs are to be included in the database, they should be included in the prototype to verify presentation. The more realistic and comprehensive the prototype, the more useful it will be.

When the prototype database is available, a group of end users is organized to evaluate it. While each user may not be completely familiar with all the capabilities of the application software, their input will be valuable in determining whether the attributes and database structure are complete and usable. A questionnaire derived from the project requirements can be used to facilitate the evaluation process.

Using the information gained from evaluation of the prototype, the schema is revised, the loading files modified, and the database recompiled. The evaluation, revision, and rebuild cycle is continued until the database is determined to be acceptable. This prototype database should be archived for future reference by moving it to another directory or renaming it.

While this iterative approach of database design, load, evaluate, and re-design may seem time-consuming, it has been proven to be the best method for creating a database that best meets the end users' requirements and is the most efficient method in the long run. The most time-consuming aspect of creating a database usually involves formatting and inputting the actual data. Revising the final database can mean revision of numerous large files.

The final prototype should be subject to a final review before data entry is begun. Designating a review committee and formalizing the procedure will help to ensure a database that meets the acceptance criteria. Final approval should include a consensus of the end users. If the database is too difficult to use or does not provide a real benefit over their current methods, they will continue to use what is familiar to them.

### **3.6 Populating the Database**

The data provider coordinates the effort of formatting the data for entry into the database. Data often comes from disparate sources and is stored in a myriad of media and formats. The process of entering or translating data into the database should include documenting the status of the source data and establishing the most efficient method of loading it into the database.

The individual values for each attribute may come from different sources. For each attribute, the data provider should identify:

- Where the source data is located
- How to acquire a usable copy of the source data
- What media it is stored on or will be delivered on
- What format it is stored in and in what format it will be delivered in

To increase the efficiency of the data loading process, it is best to group the data by format and media. Each format and media will have a particular data entry process or method associated with it. Because data can be entered from an unlimited number and type of data files, it is generally easy to accommodate data stored or delivered in different forms.

Data entry of information stored on paper may be simplified by first transferring it to a standard form. Future data acquisition for the same type of data could be entered directly into the same form. This aids in assuring data consistency and completeness. It may also be useful to store some information as documents, which can be accessed in any form or location. Web-enabled applications have greatly increased the usefulness of this method.

For each group of data, the optimum procedure for data entry or transfer of data into the database must be established. There are several ways to load data into a database, largely dependent on the software application:

1. *Load Files.* Load files are typically formatted in ASCII text files but may be any file that is used to populate materials property values into a database. They can be created manually using any word processor or text editor or translated from another electronic format.
2. *Spreadsheets.* Spreadsheet applications are often used to process raw data and to load that data into a database. This method is particularly appropriate for relational databases, which are stored in spreadsheet-like tables.
3. *Manual Entry.* Disparate bits of data or minor revisions can usually be keyed directly into the database using the software application interface.
4. *EXPRESS/XML/MATML.* These standard formats are useful for transferring data from existing software or database applications, if supported by the individual applications.

Having established the best methods for loading data from each data source, populate the database with the material property values required for each end use application.

### 3.7 Building the Database

Using the best methods for the specified database software application, a final production database is compiled for distribution to the end users. All standard database-building practices should be observed and incorporated. These techniques are unique to the type of database used and are well documented in the database administration literature.

It is important to backup the final database and to control versioning. The security of data sources and the final database should be given appropriate consideration at this point, as these items represent a significant investment.

### 3.8 Customizing the User Interface

The information gathered in the discovery phase of the database building process can be used to customize the user interface, if required. Most user interface customizations are accomplished with files that are external to the database. Customizations can include creating data-specific reports or creating views (virtual tables) that can be applied globally or on an individual basis. In most cases, these user interface customizations involve queries that are executed to extract subsets of data. Some typical database-related user interface customizations that may have an impact on the database structure, definition, or organization include:

*Units Conversion.* Database values are generally entered and stored in the units system in which they were measured. Different end-user applications may require a different unit system. The database or user interface software must accommodate this units conversion.

*Export/Import Data Mapping and Reports.* There are numerous uses for the data extracted from the database. The end use can be simply creating reports for viewing on screen or in hardcopy. Often it involves importing or exporting data to external software programs, such as analysis codes. Data manipulation may be involved during export to transform the database data into the formats required by the external program. The required transformations or mappings may influence the data type, units, or accuracy of values stored in the database.

*Database Documentation.* It is good practice to provide documentation to the end user that details the database structure and content. This documentation assists users in understanding the database and provides disclaimers or data qualifications.

*Indexing Database.* The performance of access and query functions is improved significantly by indexing the database. Indexing is not required, but highly recommended.

### 3.9 Qualifying the Database

The completed database and all associated interface customizations should meet or exceed established acceptance criteria. Quality assurance measures the database against predetermined acceptance criteria and generates feedback to the project team. The project team corrects errors and rebuilds the database. This process is repeated until the finished database and associated interface customizations meet the acceptance criteria. When the database has passed the quality assurance process, the database is submitted for final approval.

Quality assurance should view the database and interface customizations from the end user perspective, while understanding the source data, test methods, etc. If acceptance criteria were not defined as part of the project-planning phase, assemble the project team and carefully define the criteria at the earliest opportunity. Do not wait until the project is complete before defining the requirements.

Every member of the project team can provide input to the quality assurance process. However, it is probably best that the focal point for this activity not be the database builder. Just as it is difficult to edit one's own documents, often others can more easily discover errors in the building process. The quality assurance team is analogous in its functions to the database-building team:

- The project leader provides a focal point for all communications involved in the quality assurance process and coordinates the effort. He reviews the acceptance criteria and finalizes the approval procedures.
- End users verify that the database meets specified requirements. For example, that the database supplies all necessary information in usable format, that the required materials and information for each material is available, that data is easily retrieved in a timely manner, that data transfers accurately to the end-use applications, and that required units conversions are performed.
- The data provider verifies that all specified data was transferred and is stored efficiently and accurately. In addition, he should be available for verification and validation of property.
- The programmer may be required to modify data, translators, mapping files, etc. if the data validation process indicates that data translation or data reduction errors exist.
- The database builder corrects errors in the schema, load files, and customization files, compiles the database, and resubmits it to quality assurance.

**Acceptance Criteria.** The following database acceptance criteria, specific to materials data management systems, provide a minimum set of standards:

- Does the database contain all the intended materials and data? Verify that attributes have been created and populated for all the properties, materials, and pedigree information requested by each end user to support each end-use application.
- Are commonly used queries included in the user interface? Commonly used queries should be readily available in the user interface. Verify that these queries exist, are intuitive, and return values reliably and in a timely manner.
- Is the data in the database stored correctly? Verify that curve data can be extracted and manipulated, that data is stored in the correct format for the required queries, and that attribute values are within established constraints.
- Can data be exported or transferred to the required end-use applications? Verify that exported values are mapped correctly.
- Are units conversions performed correctly and accurately? Convert units for all attributes in the database; check the returned values and conversion factor for each attribute and each unit system.

## 4 COMMERCIAL DATABASE MANAGEMENT SYSTEMS

Many manufacturing organizations have programmers on staff, so designing a database management software system in-house is often an option. Cost, schedule, and maintenance issues can quickly eliminate this option. Most commercial DBMS providers can provide volumes of testimony from their customer base regarding the failures of in-house DBMS solutions. “Off-the-shelf” applications, customized to meet the specific database and interface requirements of the organization usually prove to be most cost and time effective.

In-house personnel, using the application programmatic interface (API) supplied with the software, can often readily accomplish customizing a commercial DBMS system. Additionally, most DBMS providers offer customization services as part of an implementation or installation package. Using this approach, in-house personnel can be trained and ready to use the installed DBMS system on site.

Before examining the systems commercially available, it is recommended that you carefully review the requirements for your organization. In addition to storage of in-house data, the following should be considered:

- Whether commercial data is available for use with the DBMS.
- What hardware platforms are available and supported in-house.
- Whether plans exist to link to a PDM system. If not, identify requirements for interfacing between your DBMS and analysis or design software.
- Whether interacting with the supply chain is important to the efficiency of your organization.
- Whether the DBMS will store all required data types.
- Whether you intend to disperse your data locally or globally.
- Whether the DBMS supports materials data standards embraced by your organization and industry.

The following systems were commercially available at the time of this writing. This is not an exhaustive list, but a compilation of several different approaches to the problem of materials data management. Most are supplied by companies that also offer complete implementation services. The following excerpts are derived from product literature.

***MSC.Mvision and MSC.Enterprise Mvision, by MSC.Software Corporation.*** MSC.Mvision is a suite of software applications based on a proprietary database system that is optimized for engineering materials data. Designed and built specifically for engineering applications, they include integrated X-Y graphics, printing, spreadsheet, query language, and web browser capabilities. The applications easily handle complex engineering data types such as numerical values with units, footnotes, numerical precision, images, photographs, and documents.

MSC.Enterprise Mvision provides web-enabled access to MSC.Mvision databases. Using a client-server configuration and a standard web browser, users

can view data stored in a single location, eliminating the requirement for local database installations. Designers or engineers can directly search a central knowledge collection, retrieve data, create graphs, export data to analysis codes, or link to external web sites or public-domain databases. Units conversion, footnotes, metadata, and pedigree information is displayed alongside the data values to which they pertain.<sup>13</sup> Additional features of the MSC.Enterprise Mvision Materials Information System include:

- Controlled access to proprietary information.
- Extensive customization and integration options supplement the standard user interface using HTML and Java programming.
- Integrated access from within MSC.Patran and other CAE environments.
- Integrated client capability provides integration with other computer-aided design (CAD) or computer-aided engineering (CAE) software, allowing data search and retrieve capability from within the application.
- An extensive collection of precompiled materials databases from authoritative sources offer over a half million individual materials data records, including a fully queryable version of Mil-Handbook 5.
- Applications are available for use on UNIX, Windows PC, and Linux PC.

***CentOR Software, Inc.*** CentOR Software provides business-to-business (B2B) interaction management solutions. Using web-enabled XML-based technology, its software allows customers to optimize business interactions with partners and suppliers. At the core of CentOR's application suite is the Interactive Server TM, a secure, scalable, and open standards-based platform designed for rapid development, innovation, and cost-effective reuse of ideas information and processes. CentOR's Design Collaboration product includes the following applications:

- Customer Driven Design enables collaborative modeling of product features and customer requirements, assists in prioritizing engineering activities, leverages the customer voice early in the development process, minimizes value-add features, and measures specific feature impact.
- Materials Identification and Validation enhances materials analysis early in the design process, helps designers leverage preferred suppliers and approved vendor lists, and facilitates collaboration among engineering, manufacturing, purchasing, and supplier organizations.
- Regulatory Compliance Management allows companies to stay current with interchange processes (compliance and conformance) through the aggregation of forms and information for a diverse set of compliance requirements such as Environmental Health and Safety (EH&S) for the Environmental Protection Agency (EPA), Occupational Safety and Hazard Administration (OSHA), and product development for the Food and Drug Administration (FDA).

**IDES, Inc.** IDES, Inc. provides content conversion and management for materials suppliers, focused primarily on the plastics industry. Utilizing XML technology to capture materials information for dissemination via web browsers, IDES' Content Team assists an organization in bringing product information into one current and comprehensive source for use in e-business initiatives via the Intranet and a Extranet. By incorporating the importance of global test standards and utilizing a multitude of database formats, they provide an effective system for managing technical information.

IDES also has options for manufacturers or original equipment manufacturers (OEMs) who may be implementing ERP systems or other supply-chain solutions. IDES offers customized solutions.

**M-Base Engineering + Software, GmbH.** The MC-Base material database software application is based on Java technology and is accessible by a web browser. Providing the benefits of centralized access to materials data maintenance and distribution, it makes materials data available to the extended organization. The system offers search and sort capabilities, single-point and multipoint data storage, graphics features, and complete data maintenance and administration tools.

The components of this system include an Internet browser with Java 2 support, Oracle Application Server, and an Oracle Database System. M-Base provides programming expertise for modification to their software to integrate existing in-house software and CAE programs.

**Cambridge Materials Selector (CES3), Granta Design Limited.** CES3 is designed to manage materials and manufacturing process information within an organization, providing cost savings, superior design capability, preferred list management, and fast information flow. CES3 incorporates the "design-led" selection methods of Prof. Mike Ashby of Cambridge University, allowing engineers to determine optimal choices of materials and processes. There are six main parts to the CES3 system:

- Selector, the latest implementation of the intuitive graphical method for selection pioneered by Ashby and co-workers at Cambridge University Engineering Department.
- CES Data Modules, comprised of high-quality, validated data—materials, manufacturing processes, structural sections, suppliers, references, uses, and industrial sectors.
- Constructor, the database development kit for CES3, making the system customizable and extensible.
- InDepth, providing background information about the CES system—the selection methodology, the databases, reference information, and 50 fully worked interactive case studies.
- Viewer and Weblinks, providing access to high-quality information on CD-ROM and the Internet, respectively.

CES3 is intended principally for four application areas:

- Decision support for engineers with demanding design requirements
- Management of in-house company information relating to materials, processes, shapes, standard components, or other engineering knowledge bases
- Marketing by manufacturers and distributors of materials, process equipment, structural sections, or standard components
- Education of materials selection in engineering design, process selection in manufacturing, and other related subjects

This product requires a PC with a Pentium processor, using Windows 95 or Windows NT4 or above.

***MAPP, by Matec Materials Technology Software and Data Services.*** MAPP is a database management system with an adaptable, open structured interface and search engine. It was designed specifically to enable materials scientists and engineers to develop their own materials database under Windows or for use on Apple Macintosh systems. It can be used to:

- Construct a database containing materials by trade and common name, composition, specification, and property data.
- Search for materials by any of the above entry criteria; list materials meeting maximum and minimum values for one or more properties.
- Export data to spreadsheet, word processing, or graphics programs.

## 5 MATERIALS DATA STANDARDS

Materials data compilations represent a considerable investment and, therefore, usage must be maximized. When the development of a materials database system for the dissemination of materials data, either within or outside of an organization, is considered in conjunction with the requirements for integration with other systems, the need for standardized representation of materials data becomes obvious.

There are two distinct types of standards for materials data: standards for materials test data reporting and standards for materials data exchange, including those for transfer of data in electronic format to CAD/CAM/CAE systems. Organizations active in writing standards and coordinating development for materials test data reporting are:

- ISO International Organization for Standardization (TC 61 SC 13 WG 1-6)
- NIST Office of Standard Reference Data
- DoD Technology Standards Area (Mil-Handbook 17, Mil-Handbook 5)
- ASTM Standards for Composites Materials (D20, D30, C28)

Organizations active in materials data exchange standards are:

- NIST Center for Manufacturing Technology
- ASTM Computerization of Material Property Data
- NIST Institute for Computer Science and Technology
- ACC Automotive Composites Consortium

The following summarizes the evolution of the standards most commonly used by the materials community for the standardized reporting and exchange of engineering materials data.

**IGES/PDES.** The IGES/PDES Organization was coordinated in the late 1970s from industry, government, and academia to develop standards and technology for the exchange of product information between different CAD systems.<sup>16</sup> This group focused its efforts on two projects, the Initial Graphics Exchange Specification (IGES) and Product Data Exchange Specification (PDES) using STEP. This effort resulted in the publication of IGES in 1980, which was subsequently adopted as an ANSI standard. IGES Version 5.3 was published in 1996.

A second-generation Product Data Exchange (PDE) technology, Product Data Exchange Specification (PDES), was initiated during the mid-1980s and was submitted to ISO in 1988. The international community adopted it as the basis for ISO 10303 (STEP).

Today, the ongoing PDE technology efforts include the primary Product Data Exchange using STEP (PDES), an American National Standard (ANS). This project is the primary U.S. project providing industry inputs to this ISO activity. Fourteen international standards have been created as a result of this effort. More than 20 countries worldwide have approved STEP, including all major U.S. trading partners.

The Initial Graphics Exchange Specification (IGES) defines a neutral data format that allows for the digital exchange of information among computer-aided design (CAD) systems. CAD systems are in use today in all phases of the design, analysis, manufacture, and testing of products. Since it is common practice for a designer to use one supplier's CAD system and for the contractor and sub-contractors to use different systems, there is a need to exchange data among CAD systems. Using IGES, a user can exchange data models in the form of wire frame or solid geometry representations. Applications supported by IGES include traditional engineering drawings as well as models for analysis and/or various manufacturing functions. In addition to the general specification, IGES includes application protocols in which the standard is interpreted to meet discipline-specific requirements.

Version 1.0 of the specification was adopted as an American National Standard ANS Y14.26M-1981 in November of 1981. The current version, IGES 5.3, was approved by ANSI under the new guidelines of the U.S. Product Data Association (US PRO) during September 1996. Under the latest distribution agreements with ANSI, US PRO has obtained permission to distribute IGES 5.3 in both paper and digital (e.g., CD-ROM) formats. The latest version of the IGES standard is designated ANS US PRO/IPO-100-1996.

IGES version 6.0 is slated to be the next, and final, release of the standard. The IGES project has posted a list of the Edit Change Order extensions approved

for 6.0. Current plans call for the support of activities related to maintaining the existing IGES capabilities with all new requirements being forwarded for consideration in the appropriate parts of the STEP/PDES standards.

**ASTM Committee E 49.** The ASTM Committee E 49 is responsible for one of the leading efforts in materials property data representation in computerized systems. The various subcommittees specialized in areas such as materials designation, data recording formats, terminology, data exchange, and data and database quality. The compiled set of standards is included in Volume 14.1 of the *Annual Book of ASTM Standards*.<sup>17</sup>

**ISO/STEP.** The most comprehensive effort toward standardization was the development of STEP in 1995 (formally ISO 10303; Standard for Product Data Representation and Exchange), which was designed to model all aspects of a component throughout the life cycle of the product. STEP uses a data-modeling language known as EXPRESS for its neutral format, which while originally created to facilitate automatic generation and interpretation of computer software, is also readable in ASCII format. Within this model are all the tools required for efficient data transfer, known as parts. Specifications called application protocols (APs) are used to apply the general concepts outlined in the parts to particular classes of products.<sup>18</sup> Through the implementation of APs, STEP is extensible across a wide variety of applications and industries.

The Materials Model, Part 45, defines a material as a manufactured object with associated properties in the context of its use environment.<sup>19</sup> Unlike traditional textbook views of materials with limit point properties abstracted from microscopic representative volume elements, Part 45 represents the actual property distributions in a finite volume material object as manufactured. This more robust definition is required to design robust products. The textbook definition is adequate for conceptual design (screening) and is a subset of the Part 45 definition.

The standards required to integrate the materials property data into the CAD/CAE environment require math forms to represent linear or nonlinear materials properties. Linear property models for finite element mechanical and thermal analysis are included in Part 104 and are incorporated into AP 209 for modeling metallic and composite structures. Other applicable parts and application protocols include:

- Part 42—Geometric and Topological Representation
- AP 203—Configuration Controlled Design
- AP 214—Core Data for Automotive Design Processes

The advantages of using such a comprehensive standard as STEP in a materials data management system include<sup>20</sup>:

- Ready-made data structures that are rich in detail
- The integration of dispersed data systems
- Flexibility for different purposes
- Automatic integration with different CAE systems

- More complete audit trails for the origins of data
- Increased quality assurance
- Reduced costs, liability, and risk

Finally, at the end of a product life cycle, ISO 14000 compliance is required as regulatory agencies become increasingly strict about environmental regulations.

In addition to the current international standards, work is underway on over 30 additional parts of STEP.

**Materials Consortia.** Various collaborative consortia have developed their own standards for modeling materials data, which have become *de facto* standards for the respective industry. These consortia implemented a common technology, data structure, or modeling format for the data stored in their databases. The resulting populated databases represent a competitive advantage and are generally confidential to members of the consortia. Some examples include electronic packaging materials, carbon-carbon materials for rocket engines, and creep data on steels used in the power station industry. Noteworthy efforts include:

- The Mil-Handbook 17 committee documents the standards for storage of composites test data used by leading aerospace organizations.<sup>21</sup> The Mil-Handbook 17 schema provides a structure for over 500 attributes of composites test results and processing history of the materials to which the data pertain, compliant with Mil-Handbook 17 terminology.
- The Automotive Composites Consortium and ASTM Committee E-49 collaborated to develop standards for the computerization of composite materials and metadata.<sup>22</sup> This early work provided guidelines for composites data storage, identifying the importance of metadata (also referred to as pedigree) in defining the material. Over 50 parameters are required to adequately represent a composites material test specimen. These properties serve as the basis for an audit trail when the source or history of a property is required.<sup>23</sup>
- The Computer-Aided Materials Preselection by Uniforms Standards (CAMPUS R) consortium of plastics suppliers has developed a database used worldwide for storing materials information on plastics. Provided for use on a PC, it uses a uniform database structure and interface for all participating suppliers, allowing screening of materials for new applications. All properties included in the CAMPUS database are tested to one of two international standards, ISO 10350 (single-point data) and ISO 11403 (multipoint data), parts 1 and 2, for comparable data.

**Materials Data Standardization and the Web—MATML/XML.** When considering computerized access to materials data, one must start by recognizing that hundreds of different engineering material designation schemas are used by trade organizations, standards agencies, government agencies, and individual companies. Virtually all were developed prior to the era of web-connected computers. Therefore, a natural language capability is required to search the universe

of material databases. There are no absolute standard designations available for engineering materials. Therefore, even when the same database software system is used to build a set of databases, web searches are difficult due to the different designation systems required for different material types.<sup>9</sup>

The dissemination and exchange of information on the web is typically performed using HTML (hypertext markup language). HTML, designed to describe a document's form rather than content, does provide flexibility for those in a given industry to establish their own language for their own purposes, meaning HTML is not extensible. Communities of web users rapidly reached the point where they wanted to move beyond the dissemination of information into the exchange of information.<sup>24</sup>

Recognizing these shortcomings, the World Wide Web Consortium (W3C) embarked on an effort to bring an abridged implementation of the standard generalized markup language (SGML), a language used to describe languages, to the web. The result of the W3C's effort was the February 1998 release of the version 1.0 specification of XML, the extensible markup language. XML provides:

- Extensibility, so users can define their own tags and attributes used in their documents.
- Structure, so users can define their own document-type definition (DTD), the information model for a document describing how the tags and attributes are combined.
- Validation, so users can test the conformance of their documents to the structure defined by the DTD.

Additionally, XML was designed to be easy to learn, easy to write, easy to interpret, and easy to implement; characteristics perfectly suited for use on the web. Many excellent sources of information are available on XML on the web, such as the W3C's XML pages.

There are now many applications of XML in use by different communities. Two well-known examples in the sciences are MathML, developed by mathematicians to represent mathematical notation and CML, the chemical markup language, designed to manage chemical information. In October 1999, a new effort called MatML was launched to develop an extensible markup language for materials property data. MatML permits the storage, transmission, and processing of materials property data distributed via the world wide web. The MatML Working Group, coordinated by the National Institute of Standards and Technology, represents a cross section of the materials community with members from private industry, government laboratories, universities, standards organizations, and professional societies, whose strategy includes dissemination of MatML through a variety of standards and professional organizations.

The Working Group has recently produced a working draft of the document type definition (DTD) for the markup language. The MatML DTD contains structures for transferring information concerning the material and its properties and terms for its interpretation. The DTD is the XML semantic and syntactic formalism that software will need to parse, interpret, and use the data contained

in MatML documents. The MatML DTD is soon to be subjected to application development and acceptance testing, which will be crucial in demonstrating that MatML works, testing its robustness, and serving as a guide for others interested in using MatML.<sup>16</sup> Data encoded in MatML can be utilized by web browser components, import filters to spreadsheet and database programs, import filters to CAE software, parsers, and editors.

## 6 SUMMARY

A materials data management system can significantly improve the efficiency and profitability of an organization when strategically integrated into an organization. Its success depends upon the full commitment of management, an implementation that supports the company's business objectives, and careful planning to provide access to the required data for each end use function throughout the product life cycle. Optimized use of commercially available systems, customized to meet the functional and integration requirements of the organization, can help to ensure a positive return on investment. Utilization of recognized database management practices and the increased ease of data transfer between software applications offered by the use of established industry standards can help to create a system that is user friendly and easily adopted by the entire organization.

### 1 INTRODUCTION

No article can be produced in today's economy without access to substantial procurement information on the constituent materials specified by engineering for its manufacture. Furthermore, today's demands for environmental protection and conservation require materials information of other sorts, both for disposal of the article itself and for the scrap generated during its manufacture. The needs and sources for these types of information are summarized in Fig. 1, which displays the role of materials information throughout the design-manufacture-use cycle. In this chapter we will detail the kinds of information needed for materials procurement and disposal and summarize the available sources for this information. Finally we review some current issues affecting materials procurement—globalization, e-commerce, and “just-in-time” logistics management—the function of information in optimizing the business impact of each issue, and the consequent new demands on information—currency, computer access, etc.

### 2 PROCUREMENT INFORMATION

***Designation and Specification.*** The task of materials procurement in an industrial enterprise cannot be likened to that of a grocery shopper who makes a simple list (apples, bread, eggs, etc.), drives off to the local supermarket, and makes acquisitions by visual inspection and on-the-spot price comparison. In contrast, the industrial purchasing agent must first know how is this material

Fig. 1 Information needs and sources at various steps in the design-manufacture-use cycle.<sup>4</sup>

identified, who are the leading producers and their addresses, in what unit quantities is it sold, to what specifications or standards must it conform, etc. To answer the first question, the agent must know the most common designation for the material—international, national, trade association, or other—and its equivalence in other designation systems. Various directories and cross-reference guides have been developed for this purpose, a summary of which is provided in Section 3. A typical example of a family of equivalents is shown in Table 1.

Nominal equivalence, as set forth in a cross-referencing table or by chemical composition as in Table 1, may not suffice. Thus any material offered by a prospective supplier, whose specification is not explicitly that called for by the design engineer, should be tested for critical properties and a sign-off obtained from engineering prior to purchase. The sources cited in Section 3 are primarily cross-reference guides and seldom offer more than a brief summary of a specification. Therefore, to assist the engineer in determining the equivalence or acceptability of the material in question, resort must be made to the full specification for the material. These may be obtained from the issuing body—International Organization for Standards (ISO), American National Standards Institute (ANSI), American Society for Testing and Materials (ASTM), Deutsches Institut für Normung (DIN), British Standards Organization (BSO), etc. Conveniently, a very comprehensive collection of standards and specifications of all types is maintained by Information Handling Services, Englewood, Colorado, which can provide printed copies of any selected specification for a nominal charge.

The purchasing agent should work with the engineer to secure the most cost-effective material. In particular, effort should be made by a company to avoid “specials” and to try whenever possible to adopt a standard or specification already established by an organization at a higher hierarchical level, that is, a trade association, professional association, or national or international standard. Whenever necessary to be included in a specification, the test method or quantitative inspection technique cited should be one recognized nationally, for example, an ASTM standard. The subject of standards and specifications for materials has been discussed by Westbrook.<sup>2</sup>

**Materials Sources.** Having identified the material needed and the specification(s) governing its properties, the purchasing agent must consider possible sources from which it might be obtained. These should include both sources local to the plant of the procuring organization, national sources, and international sources. Whether or not a given vendor is a viable source will depend on stocking policies, delivery schedules, price, etc. Economic aspects are discussed below under costs. General guides to materials sourcing are as follows:

**Costs.** Actual costs of a procured material are determined by interaction between the purchasing agent and the supplying vendor. These are not necessarily fixed and neatly listed in the supplier's catalog but may depend on a number of factors of which the purchaser should be aware. These include: Is the material regularly stocked or only available on special order; is price affected by size, shape, or surface finish; are there quantity discounts or order quantity minima; what are the normal delivery schedules; are there particular features required that the vendor company would regard as "specials"; etc. General information about material costs and price trends may be found in the sources

given above, particularly, *American Metal Market*, *Chemical Economics Handbook*, the *Roskill Metals Databook and Reports*, and the *Serjeanson book*.

**One Company's Reduction to Practice.** For more than 70 years the General Electric Company has had a formalized, comprehensive, reference system for the materials information needed in its diverse manufacturing operations. This system is known as EMPIS, an acronym for Engineering Materials and Processes Information Service, and is organized in a tripartite structure, sometimes referred to as the three legs of the materials information stool: engineering properties, specifications, and data for ordering. A fuller description is provided by Westbrook.<sup>3</sup> The part that is relevant here is the Data for Ordering section.

A typical page for a single material among the more than 25,000 materials covered in GE's EMPIS system is shown in Fig. 2. In addition to the EMPIS material number, title, and scope and designation sections, which are similar to

**METALLIC MATERIALS**

B6B3

DATA FOR ORDERING August 22, 1980★

COLD WORK TOOL STEEL, GENERAL PURPOSE; Mn-Cr-W, UNS T31501 (AISI O1)

GE Material B6B3 identifies oil-hardening, non-deforming manganese-chromium-tungsten tool steel, similar to UNS T31501 (AISI O1), as follows:

| GE designation | Form                      | Condition              |
|----------------|---------------------------|------------------------|
| B6B3A1         | Castings                  | Annealed               |
| B6B3C1         | Bar                       | Hot-rolled, annealed   |
| B6B3C2         | Bar                       | Cold-drawn             |
| B6B3D1         | Cancelled<br>(use B6B3D2) |                        |
| B6B3D2         | Drill rod                 | Standard ground finish |
| B6B3F1         | Plate                     | Hot-rolled, annealed   |
| B6B3G          | Flat stock                | Annealed, ground       |

Each supplier, listed below, has received copies of Specification B6B3-S8 and has been identified as a source of supply for this material. ♦

Orders for this material should specify:

Material name - Tool steel  
Designation - GE Material B6B3 (add proper suffix)  
Specification - B6B3-S8 ♦  
Quantity and size  
To whom certificate of test should be sent, when requested.

Source of supply for GE Material B6B3: ♦

GENERAL ELECTRIC

★ Supersedes issue of  
April 7, 1970Fig. 2 Typical data for ordering sheet.<sup>3</sup>

the corresponding sections of the specification document, the Data for Ordering sheet contains a checklist, a reference to applicable documents, a list of tested sources of supply for each of the various grades covered by the specification, and when applicable the appropriate supplier's designation for the product. (The supplier's designations are not a part of the specification but are included on the Data for Ordering sheet as clarifying information).

A checklist is provided that tells the buyer at a glance exactly what must be written on the purchase order and what documents are to be included with the order to completely define the desired material. The list of suppliers provided includes only those that have previously delivered conforming material to the General Electric Company and are added to the list at the request of operating components of the company that testify to compliance. To this extent they are treated as sources of supply. However, the list is not to be construed as an "approved" list of suppliers, nor as an all-inclusive list. Buyers are encouraged to develop additional sources of supply—particularly for critical or large volume applications—and to report satisfactory experience for subsequent addition to the list of suppliers. Each supplier listed on the Data for Ordering sheet is placed on an automatic distribution list and receives updated copies of each specification for which the supplier is listed. Therefore, when buying from a listed supplier, it is not normally required that a copy of the specification accompany the order.

In many cases the Data for Ordering sheet contains special notes, hints, and suggestions for facilitating procurement, minimizing costs, and standardizing sizes and lots. These are of many different kinds but include, for example, sizes stocked by listed suppliers, cost information, minimum order quantities, delivery schedules, features that represent "specials," etc.

#### 4 MATERIALS DISPOSAL

Proper disposal and recycling of materials serves several different objectives: conservation of resources, reduction of energy consumption, lowered materials costs, and regulatory compliance [local, state, and national, e.g., Environmental

Protection Agency (EPA) regulations]. Specific instances include the separation of valuables, e.g., platinum from automotive emission controls, and the separation of hazardous or deleterious contaminating elements, e.g. Pb, Hg, Sn, and Zn. Materials scrap is distinguished as to that resulting from obsolete or worn-out product (obsolete scrap) and that internally generated during manufacturing (prompt scrap), the latter being further broken down into that which is immediately internally recycled (home scrap) and that which is input to the scrap recycling industry (purchased scrap). Throughout all these movements of potentially useful material, information is needed as to the form, composition, and source of the scrap.

Some industries even produce scrap specifications; the iron and steel industry alone has more than 20 such documents covering different grades of ferrous scrap. To realize the highest value from scrap recovery and recycling, or to avoid penalties from improper disposal, thorough identification is needed. This in turn requires reference information on physical properties (color, density, hardness, magnetic behavior, thermoelectric properties, spark characteristics, etc.) and chemical properties (qualitative spot tests, quantitative chemical analyses, or optical and X-ray spectroscopies). If the scrap cannot be explicitly defined as to the particular material (alloy, solution, blend, etc.), then it will be used in a downgrading operation, with lowered cost recovery and heightened possibility of contamination. Some particular sources of information on materials disposal and recycling are listed in Section 5. Other may be found in Refs. 4 and 5.

## 6 CURRENT ISSUES

In Section 1 we mentioned some current issues placing new demands on information. Globalization is one such issue. Today, not only are many materials being sourced from overseas, but entire products or components thereof are being manufactured overseas, but to American designs and specifications. The need for information relative to equivalency of U.S. versus foreign materials test methods, delivery schedules, etc., is obvious. Some relevant information sources were included in Section 2. Others may be located through the International Forum on Globalization<sup>6</sup> and other Websites.<sup>7,8</sup>

A second factor is the growing use of so-called e-commerce: doing business almost entirely electronically rather than via printed documents or interpersonal information exchange. The extent of the use of e-commerce varies between fields, but current estimates are from 20–50% of all business conducted in nearly all fields and growing rapidly. This circumstance does not alter the kind or amount of material information needed but puts new demands on its currency and places enhanced emphasis on information already in electronic form.<sup>9–11</sup>

Finally, another current trend is that of "just-in-time" logistics management.<sup>12–15</sup> By this term is meant that the materials purchaser chooses not to buy and store materials at his plant until needed by manufacturing operations but rather contracts with one or more vendors to deliver a needed material on a continuing basis, obviating on-site storage and its associated costs, and feeding that material immediately upon receipt into the manufacturing operation. Again the associated information is not different in kind from that needed for traditional manufacturing, but new emphasis is placed on currency and intimate mutual understanding of information exchanged between vendor and manufacturer.

One of the daunting challenges that face a designer when making a material selection is knowing what properties are the most critical for a given application. Assuming that the appropriate properties can be chosen, the designer next needs to be able to find the properties for each metallic material of interest (a challenge in itself) and then interpret the values relative to the design requirements. This requires that the designer have rudimentary knowledge of both the properties and test methods as well as an understanding of how to interpret the properties in the design context.

The purpose of this chapter is to provide some of the basic background for how metallic materials are mechanically tested. The goal is not to provide enormous detail for each different type of property; other sources, for instance Ref. 1, can provide this. Rather, the intent is to provide sufficient basic information so that the reader understands what the purpose of the mechanical test is, what mechanical property typically results, and what the corresponding design implication is.

The complexity of metallic materials testing and the specific technical language required can be confounding, especially to engineers not intimately familiar with the field. Those of us in the field also can confuse each other as new methods, terminologies, and approaches develop and are adopted. Luckily, there exists an organization whose mission in part is to minimize this type of misunderstanding.

The American Society for Testing and Materials (ASTM) is one of the world's largest standards development organizations with over 34,000 members responsible for more than 10,000 standards. The breadth of these standards is enormous (74 volumes), covering not only test/evaluation procedures but also standardization approaches for designating metals, paints, plastics, and the like. Originally developed in 1898, this independent, not-for-profit organization serves as a forum for producers, users, consumers, and others in developing voluntary, consensus standards. In practice, a hierarchical committee organization develops the standards initially with a group of experts providing a draft standard. This draft is subsequently balloted by ASTM and does not become a standard until all concerns raised during the voting process have been fully addressed.

The test-related standards that ASTM publishes help to ensure that mechanical properties generated in one laboratory are consistent with those generated in another laboratory. This consistency is critical from a design point of view since specific property values are typically extracted from numerous sources, and knowing that consistent methods were used in generating these properties is subsequently crucial. The majority of the ASTM standards related to metals test methods and discussed in this chapter are contained within Ref. 2.

Knowing where to look for the standard does not necessarily imply that it is easy to know which property is the most germane for a given design. For instance, under the classification "fracture testing," there are 16 separate standards in Ref. 2, all very different and evaluating disparate quantities such as crack-tip opening displacement, plane-strain fracture toughness, surface crack toughness, dynamic tear properties, and the like. The fundamental characteristics of the design scenario involved and the candidate metallic materials considered will dictate which fracture property is suitable. In a case such as this where many different test methods are available, selection of the appropriate test standard is complex and beyond the scope of this elementary treatise.

Finally, ASTM also provides other resources to ensure that the properties required are available. In particular, the *Directory of Testing Labs*<sup>3</sup> provides a state-by-state listing of laboratories that are available to perform materials testing. The laboratories are identified by the type of test performed, with an index cross-referenced to specific test methods. Moreover, a brief synopsis of the lab, including scope of testing, facilities, and staff, is also provided to allow differentiating between the different available choices.

## 1 MECHANICAL TEST LABORATORY

During mechanical testing, a component or material is loaded with either displacement or force, causing a deformation and associated mechanical response to occur. The loading occurs at a design relevant rate (impact, static, or cyclic), and the test is typically performed in the most suitable environment for the end use of the component. The two key components in this process that make up the primary constituents in a mechanical test lab (Fig. 1) are the test machine required to apply the specified loading as well as the sensors and instrumentation used to measure the behavior of the test article.

### 1.1 Test Machines

The test machine, or loading frame, is used to apply stress (or strain) resulting in axial tension or compression, bending, shear, torsion, or pressure. Although

**Fig. 1** Typical material test lab containing numerous servohydraulic test frames.  
(Courtesy of Fracture Technology Associates)

a variety of different loading systems are available, the most common is the universal testing machine, which allows all of these different types of loading types by use of different test fixtures and load train components. Load is applied through a hydraulic piston and cylinder (servohydraulic machine) or with precision machine screws (screw machine) driven by an electric motor and gear box system. Although screw machines have lower load capacities than servohydraulic systems (generally 125 kips or less), their displacement stability, accuracy, and precision is better than typically observed with servohydraulic systems. Nevertheless the advantage of the more common servohydraulic systems is the rapid rate of response necessary for many types of tests (e.g., any type of cyclic testing, including fatigue and fracture applications).

For the case of servohydraulic machines, the actuators are typically double-ended allowing tension and compression of the load train. The displacement rate of these machines range from nearly static to approximately 350–1000 in./s. The actual highest rate possible for a given machine/specimen combination is difficult to assess since it depends upon the actuator size, flow rating of the servovalve, as well as the supply pump, plumbing configuration, and control system parameters. Servohydraulic test machines range in size but are typically available from 1 kip to 1000 kips or more.

The control of screw and servohydraulic machines is accomplished through dedicated microprocessor-based electronics. Controllers generally fall into two categories: the older generation (but stable and cost effective) analog controller and the newer digital controller (Fig. 2). In the strictest sense, an analog controller needs a signal source to drive it, typically either a built-in function generator or an external computer for complex waveforms or more stringent control requirements. Whereas machine control in this case is with analog electronics, in the fully digital system closed-loop control is achieved with a computer running software designed to perform the test of interest. The digital systems are typically provided with a suite of programs designed to perform a wide variety of standard test protocols.

A test machine is incomplete without a range of grips and fixtures suitable for inserting a test specimen into the load train of the frame. Although the

**Fig. 2** Servohydraulic test frame and digital controller. (Courtesy of MTS Corporation)

majority of the ASTM test standards address fixtures and grips in some manner, inevitably the hardware available in a given laboratory is diverse and varied, consisting of both standard and hybrid fixtures whose functionality has been proven through repeated use. Versatile pneumatically or hydraulically actuated mechanical clamp grips constitute one of the more popular types available.

## **1.2 Sensors and Instrumentation**

The sensors and instrumentation in a lab are designed to measure mechanical behavior. Perhaps the most commonly used sensor is the load measuring device, also called a load cell. Load cells are placed in series with the specimen in the loading train and can come in a wide variety of sizes and configurations. Normally, threaded couplings are available on either side of the load cell to attach fixtures. Inside the load cell is an instrumented transducer, typically using strain gauge technology to relate applied load to a resistance change suitable for sensing.

Although numerous nontraditional methods and systems exist for measuring displacement or strain,<sup>4,5</sup> the most common method is based on a sensor that provides output based upon strain gauge technology. An example of this is the highly reliable modern material test extensometer (Fig. 3). This device, fastened to the specimen by mechanical clamping, is used to accurately measure displacement between a pair of short knife edges affixed to the gauge length of the specimen. Another type of displacement gauge is the clip gauge, which is basically a spring-loaded extensometer with longer arms. These devices are

**Fig. 3** Extensometer (displacement measurement device) mounted on a tensile specimen.

extremely accurate and robust, but they do have environmental limitations to some extent due to their reliance on strain gauge technology.

Sometimes it is also useful to mount strain gauges directly on the surface of the test specimen to infer localized behavior. Furthermore, linear variable differential transformers (LVDTs) and capacitive coupling-based displacement devices are commercially available for use in the most aggressive environments. In addition, noncontact optical systems (laser or charge coupled device, CCD, camera based) can also be used to obtain displacement measurements. Recent improvements in computer processor speed, CCD camera size, as well as more affordable random-access memory (RAM) and disk storage makes these vision-based technology methods more desirable now more than ever before. The preponderance of optical systems and lack of any standardization in the core technology has resulted in recent ASTM standards activity and a draft standard that defines the relevant terminology.

Data acquisition tools have also benefited greatly from the recent advances in personal computers. Newer data acquisition systems tend to be more flexible than the older, device-dependent applications. The most popular platform for application building currently appears to be the LabVIEW (National Instruments, Austin, TX) programming environment. The LabVIEW platform provides a graphical, icon-based environment to build and modify applications that are more device/board independent and well suited to typical complex process, and data acquisition requirements.

Some of the most complex tests performed in a mechanical test laboratory are fatigue and fracture evaluations of metallic components and materials. These tests usually require highly specialized, custom software to control the test machine, take the data, and analyze the results. It is always difficult to know *a priori*, without extensive experience performing these tests, what data acquisition parameters are the most critical. For this reason a recent guide, ASTM E1942, has been developed that assists a user to understand the limitations of instrumentation and data acquisition systems, especially as related to cyclic fatigue and fracture mechanics testing. Furthermore, this standard is also useful for the segment of the test community not familiar with fatigue and fracture tests, since it provides a practical guide for understanding data acquisition performance.

## 2 TENSILE AND COMPRESSIVE PROPERTY TESTING

The tension test, defined for metallic materials in ASTM E8, is perhaps one of the simplest and most common tests of mechanical behavior. The test is conducted by gripping each end of a reduced section specimen and slowly pulling it until catastrophic failure occurs. Several sample specimen geometries (round and flat, threaded and smooth shank), conventionally described as “dogbone” specimens by virtue of their reduced section geometry, are shown in Fig. 4. Moreover, tension test specimens are sometimes notched in the center of the gauge length as described in ASTM E338 and E602. These tests are useful for determining how the given metallic material behaves in the presence of a stress concentration. Furthermore, results from these tests have also been related to fracture mechanics parameters for a given material.

In a tensile (or compressive) test, the applied load and displacement (or strain) in the gauge section is used to develop a plot of the stress–strain behavior using the specimen geometry and calibration constants of the transducers employed during the test. One challenge during tensile testing is measuring elongation to

**Fig. 4** Several sample specimen geometries for tensile testing in accordance with ASTM E8. (Courtesy of the Instron Corporation)

high strain levels while still having sufficient sensitivity in the elastic region. It is therefore not uncommon to utilize two strain transducers as shown in Fig. 5. Special high-gain strain gauges or transducers are typically required to provide sufficient sensitivity and resolution in the elastic region to derive a Young's modulus value. This is contrasted with conventional extensometry, which is usually used to measure higher levels of strain, even 20% or higher. Alternatively, two extensometers, one measuring behavior over a small range while the other configured for a large range, can be mounted on a single specimen. One advantage with this approach is that strain differences as a consequence of different gauge lengths, due to issues such as strain localization, is greatly reduced since each extensometer can have the same basic gauge length but be calibrated to different ranges.

During tensile testing, the ultimate strength is the largest applied stress measured in the specimen section. The proportional limit, often called the yield strength, indicates the onset of plasticity where the assumption of linear stress-strain behavior is violated. Since there are many definitions of proportional limit (e.g., the conventional 0.2% strain offset method or the API approach<sup>6</sup> using the stress corresponding to a specific strain level), it is imperative that the physical meaning of the limit be clearly defined when presenting the results. Moreover, post-test measurements made on the gauge length and fracture surface of the specimen are used to quantify the ductility of the specimen. Ductility is the ability of a material to deform plastically without failure occurring. Ductility parameters include percent elongation and percent reduction of area.

The mode of failure can also sometimes influence the strain results obtained. For instance, if the metallic material tested tends to exhibit highly localized plastic deformation, the region of confined necking results in either higher or lower effective strain if the gauge length is short or long, respectively. On the other hand, if deformation is equally distributed along the gauge section, the

**Fig. 5** Example stress-strain data from a tensile test from a pipe material tested at 325°F.

strain data exhibits no gauge length dependence. Obviously, the potential exists for misinterpretation when comparing stress-strain behavior from one sized specimen to another. Therefore, it is important to ensure that specimen size is constant when performing a relative comparison of properties from one condition to another or between metallic materials.

Compression testing is typically performed on short cylindrical specimens (ASTM E9). Care must be taken during testing to minimize the influence of both buckling and barreling, two modes of behavior that can corrupt compression test results. Buckling is prevented by minimizing the ratio of specimen length to diameter (typically in the range of 1–2). Load train alignment is also a critical feature of these tests. Alignment is often practically achieved by loading the specimen through a spherical joint so that slight, nearly unmeasurable misalignment will not cause buckling. Barreling results from the friction between the end faces of the specimen and the loading platens. Friction is minimized by using lubricant and machining concentric rings on the end of the specimen to trap the lubricant and keep it from squeezing out.

### 3 CREEP AND STRESS RELAXATION TESTING

Creep and stress relaxation properties are critically important for high-temperature applications. Without knowledge of these properties, both air- and land-based jet turbines, internal combustion engines, and even some electronic equipment could not be adequately designed. Furthermore, there is always increasing pressure to develop new metallic materials with better performance at high temperature so that operating temperature in these applications can be increased to yield higher efficiencies.

Creep deformation is examined by applying either a constant load or a constant true stress to a material held at a specified temperature. When the material is first loaded, a small permanent loading strain occurs and the creep strain rate gradually decreases. This portion of the creep strain versus time plot is called primary creep (stage I). This is subsequently followed by secondary (or also steady-state or stage II) creep with the highest rates observed in the final tertiary creep (stage III) immediately before failure. These three regions of the creep curve are shown schematically in Fig. 6. Whereas the test methods are described in detail in ASTM E139, the primary components of the test include a static load frame, furnace, and high-temperature extensometry.

The test specimens are similar to those used in a quasi-static tensile test, although the actual geometry used is often controlled by the metallic material form available. Static dead-weight machines are typically employed for this type of test, as shown in Fig. 7. The frames usually have a balance beam to magnify the load applied to the specimen by a factor of between 2 and 25. All of the pull-rod and coupling fixtures employed are manufactured from high-temperature alloys impervious to the environment used during the test. Tubular, electric resistance furnaces are usually used with the number of zones typically dependent upon the size of the specimen. Special attention must be made to ensure minimal thermal gradients and uniform temperatures applied to the specimen.

The measurement of gauge length deformation is typically critical during a creep experiment. If temperatures are sufficiently low ( $<400^{\circ}\text{F}$ ), conventional

**Fig. 6** Schematic of the different regions of a classic creep curve.

**Fig. 7** Loading frame to apply static (or extremely slow cyclic) load conditions.  
(Courtesy of the Instron Corporation)

extensometry as used in tensile tests can be used on the specimen. However, higher temperatures are usually involved for most metals, which necessitates using LVDT, capacitive, or other types of displacement measurement transducers. The most common transducer is the LVDT coupled with linkages that reach up through the furnace to attach to the specimen. Special care must subsequently be taken to ensure that the displacements measured actually correspond to gauge length deformation and are not biased by linkage or transducer effects.

Stress relaxation testing (ASTM E328) is similar in many ways to creep testing except that the applied boundary condition is a constant displacement (as opposed to a constant load). This type of test is more suitable for metallic materials that have significant constraint and hence exhibit little strain increase as a function of time. One example of this is a high-temperature bolted joint where a displacement boundary condition is first applied and then the stress relaxes with time. Testing times include both long-term (months or more) at the service temperature and accelerated tests (days) at more aggressive thermal conditions.

Creep and stress relaxation testing can also be performed on specimens with a more complex stress state than simple tension. Examples include compression testing (typically using a carefully machined cylindrical specimen similar to that described earlier for quasi-static compression testing), bend testing (e.g., with a cantilever beam specimen), or even torsion testing. Testing has also been performed on tubular specimens that are subject to complex, multiaxial stress states.

#### **4 HARDNESS AND IMPACT TESTING**

This section addresses two mechanical test methods that are used to indirectly determine the tensile and toughness properties of a metallic material. As with any indirect test method, there are well-known limitations to these techniques, but they are clearly offset by the reduced cost and increased efficiency of the indirect methods. The test methods, as well as their limitations, will be explained in more detail in this section.

Hardness refers to a material's ability to resist deformation when loaded by an indenter. The indenter can differ in geometry; for instance, it can be conical (the Rockwell test), spherical (Brinell), or pyramidal (Vickers and Knoop). For metallic materials, hardness is directly proportional to the yield stress of the material. Nevertheless, conversions are readily available to relate hardness to ultimate tensile strength (most commonly for steel although other conversions for different metallic materials do exist). Hardness testing (ASTM E6, E10, E18, E92, E1842, and others) is industrially attractive since the testing is rapid (<20 s), low cost, nondestructive, and generally does not require a machined specimen. As a consequence of these issues, hardness is often used as an industrial screening tool to ensure metallic material processing control. An ASTM standard (E140) exists to convert between the different superficial hardness and conventional hardness scales.

The majority of hardness testers (e.g., those shown in Fig. 8) utilize dead-weight, springs, or (infrequently) closed-loop computerized systems. Although many testers provide output on an analog meter, bench-top units with digital readouts (sometimes with an interface for a PC) are generally more popular today. When the component being hardness tested is too large to practically

**Fig. 8** Hardness testers including (a) a benchtop and (b) portable unit.  
(Courtesy of the Instron Corporation)

position onto the anvil of the tester, portable test units are available to locally measure hardness. A typical portable hardness measurer is shown in Fig. 8*b*. Regardless of the type of hardness tester used, care must be taken to ensure that the system is in proper working order by using commercially available calibration blocks.

Although hardness testing is relatively simple, accurate measurements depend greatly on careful attention to detail. The anvil should minimize the contact area with the component. Surface finish can sometimes be of paramount concern; for 100–150 kgf, a finish ground surface is sufficient whereas for a 15-kgf load, a polished or lapped surface usually is required. Surfaces that are ridged due to machining or that exhibit loose, flaking scale can yield incorrect hardness results. The test surface should be perpendicular to the indenter since even slight ( $<5^\circ$ ) angular deviation can cause hardness to shift by several points. Indenter size should be chosen with the underlying grain structure of the metallic material in mind. In general, the indenter should be larger than the grain size if a macroscopic measurement of hardness is desired. Finally, metallic material homogeneity is also important since the indenter effectively samples a region approximately 10 times deeper than the depth of the indenter penetration.

Instrumented indentation testing is a more recent method developed to derive more extensive data from effectively a hardness test. During this type of testing, the instantaneous load–displacement data is recorded continuously. The measured data can be related to such things as elastic modulus, yield strength, and strain hardening exponent. Highly empirical punch test methods are also continually evolving to relate local deformation behavior to properties such as fracture toughness.

Since some percentage of loading is inevitably dynamic and components often have to be designed to survive high loading rates typical during an accident, dynamic fracture testing can ensure structural integrity under this type of loading. During impact testing, a pendulum machine (example shown in Fig. 9) with a striker is typically used to impart high energy to a notched sample. The notch toughness of the specimen, typically a flat bar with a carefully machined notch of various geometries, is measured in terms of the absorbed impact energy that causes fracture in the specimen. Some other parameters that are commonly examined include fracture appearance and the deformation noted on the surface of the specimen. The independent variable controlled during testing is most often temperature. A typical energy–temperature curve for A36 steel is shown in Fig. 10 contrasting the typical difference between slow bend tests and rapid impact results.

The Charpy and Izod impact tests both utilize pendulum loading albeit with specimens of slightly different geometry, especially as related to the specimen notch dimensions. The primary difference between the two tests though is that the Charpy V-notch (CVN test as defined in ASTM E23) specimen is three-point loaded whereas the Izod specimen is cantilever loaded.\* Of the two methods, the CVN test remains the most popular method available, and manufacturing

**Fig. 9** Example of a pendulum impact machine. (Courtesy of the Instron Corporation)

\*Both machines were developed in the beginning of the twentieth century although Charpy was a Frenchman and Izod was an Englishman.

Fig. 10 Impact test results illustrating CVN energy versus temperature curves for A36 steel.

lot release requirements using CVN data are actually written into many metallic material specifications. The CVN test is rapid and low cost; the most expensive part is machining specimens although commercial machining templates to ease fabrication are readily available.

Two other impact tests include the drop-weight (ASTM E208) and the drop-weight tear test (DWTT as per E436). During drop-weight tests, a series of experiments are performed where different specimens at a range of temperatures are impacted with a guided, free-falling weight dropped from a fixed height. The key finding is the nil-ductility transition temperature (NDTT), which is the maximum temperature where fracture was observed. The DWTT test is similar to the drop-weight test although the specimen used is slightly larger and the test fixturing is very different. The fracture surfaces are evaluated and the percentage of shear quantified. The temperature at which 50% shear occurs is loosely defined as the ductile-to-brittle transition temperature.

CVN testing can also be performed with a fatigue precracked specimen to eliminate the notch acuity and depth restrictions inherent to the standard CVN specimen geometry. Considerable effort has also been recently expended developing instrumented impact testers to record more data. Nevertheless, the primary shortfall with most of the impact test methods is (a) the relatively small specimen size (relative to component size) and (b) the high degree of empiricism used to relate the results to metallic material properties. These disadvantages are offset by the simplicity and low cost of the test, particularly for production environments where the test can be used effectively as a quality control tool.

5 FRACTURE TOUGHNESS TESTING

The foregoing discussion introduced the concept of notch toughness, defined loosely as the energy required to initiate a running fracture from a machined notch. This is an important design parameter since nearly all structures contain notchlike stress concentrations. However, in the strictest sense according to the

science of fracture mechanics (the study of cracks), fracture is broadly classified as either brittle [governed by linear elastic fracture mechanics concepts (LEFM)] or ductile [elastic plastic fracture mechanics (EPFM)]. Fracture toughness is the ability of a material to withstand unstable crack propagation (e.g., fracture) assuming of course the presence of a crack. Fracture mechanics provides the theoretical underpinning that relates the following quantities:

- Magnitude and range of the remote applied stress
- Geometry of the component
- Morphology (size and shape) of the crack

to what is loosely termed the “crack driving force,” or stress–intensity factor  $K$ . Detailed stress analyses of cracks have shown that the magnitude of the local crack-tip stress field is proportional to this  $K$  parameter. Although  $K$  applies for LEFM, in the case of EPFM there exists another similitude parameter that is termed  $J$ .

Fracture toughness testing requires closed-loop, computer-controlled servo-hydraulic test equipment and a suite of accurate displacement extensometers. Virtually all tests are computer controlled due to the complexity of the test and the requirements for recorded data. As a minimum, most fracture tests require measuring the applied load and some displacement measurement across the crack. Most tests are analyzed by custom software developed specifically for the particular test. The most common fracture toughness test is the plane-strain fracture toughness measurement, which yields the  $K_{Ic}$  parameter as described in detail in ASTM E399. For an ASTM valid  $K_{Ic}$  value, the loading must be such that there is no significant plastic deformation (specifically, the plastic zone at the tip of the crack is less than 2% of the thickness and total crack length). The plane-strain requirement implies that the fracture toughness specimens tend to be quite thick, most are commonly greater than 0.5 in.

Although E399 allows a variety of specimens, the most commonly used is the compact-tension specimen, a pin-loaded, edge-notched geometry. The specimen is first precracked under fatigue loading to ensure that the crack tip is sufficiently sharp for the fracture test. The specimen is then loaded to failure by a constant displacement ramp applied between the pins. During the test, the load and crack mouth opening displacement (CMOD) is measured. Two sample load–displacement plots are shown in Fig. 11. In Fig. 11a, the behavior is more brittle with catastrophic failure at peak load. Conversely, in Fig. 11b the trend is more suggestive of a ductile and somewhat more stable material with slow crack advance gradually relieving load as the test progresses past the point of maximum load.

Determining a  $K_{Ic}$  toughness from the load–CMOD data requires fitting the initial linear portion of the data and plotting a 5% secant offset to that linear region. The intersection between the measured load–CMOD data and this secant line defines the critical load. This graphical construction is evident in Fig. 11a. However there are stringent limits for qualifying the conditional  $K_q$  toughness as an ASTM-valid  $K_{Ic}$ . Most importantly, the crack length and thickness are required to be sufficiently long to satisfy the small-scale yielding criteria de-

**Fig. 11** Two load-displacement plots from  $K_{Ic}$  fracture toughness tests conducted on beryllium at elevated temperature.

scribed earlier. Furthermore, nonlinearity is minimized by requiring that the critical load (corresponding to  $K_q$  and denoted by  $P_q$ ) must be no less than 90% of the maximum measured load. The two sets of data indicated in Fig. 11 are clearly invalid since the conditional  $P_q$  load is too low relative to the maximum measured load.

Whereas  $K_{Ic}$  applies for thicker, more constrained sections where catastrophic fracture occurs rapidly, a different  $K_C$  fracture test (ASTM E561, also termed a  $K-R$  curve) applies for thinner structure where slow stable crack extension precedes unstable fracture. The test specimen geometry typically used is a wide, center cracked panel precracked at low loads to generate a sharp fatigue crack suitable for fracture. The specimen is monotonically displaced similar to a  $K_{Ic}$  specimen while recording load, CMOD, and often some parameter such as electric potential drop that can be used to instantaneously provide crack length measurement.

The resistance curve, also called an  $R$  curve, is then generated by plotting crack driving force  $K$  against crack extension, termed  $\Delta a$ . Crack extension is defined as the sum of the physical crack length change, usually derived from either compliance (stiffness) or some other nonvisual crack length indicator, plus the half plastic zone size. Since the stress state is typically something more like plane stress, the plastic zones as observed on the surface of the specimen tend to be quite large. An example  $R$  curve is shown in Fig. 12. The  $K_C$  value is defined as the  $K$  magnitude at the tangent intersection between the  $R$  curve and lines of constant load plotted in  $K$  versus crack length (or crack length extension) space. This load represents the maximum level that can be achieved before the crack extends (often unstably) and structural integrity is lost. A careful exami-

**Fig. 12** Example  $R$  curve from a  $K_{IC}$  fracture toughness test performed on stainless steel.

nation of the data in Fig. 12 clearly illustrates that some crack growth was apparent in this metallic material since catastrophic failure did not occur at the point of instability.

Fracture toughness testing in the elastic-plastic regime is time consuming, not trivial, and requires advanced instrumentation to yield excellent results.<sup>7</sup> After conducting and analyzing the test, the goal is to generate an  $R$  curve, similar to that described earlier for the  $K_{IC}$  testing, as shown in Fig. 13. However, instead of  $K$  on the abscissa, the  $J$  parameter is included. The  $J$  parameter is calculated by including an elastic portion related to  $K$  combined with a nonlinear portion related to the area under the load–displacement curve (with respect to load-line displacement). The plane-strain, elastic plastic  $J_{IC}$  parameter measures the onset of instability, in this case corresponding to the point where the crack has advanced a certain amount (after blunting) on the  $R$  curve (note this instability criteria is very different than that described for  $K_{IC}$ ). It is often the case in this type of test that slow, stable cracking will continue as the specimen is displaced and the load gradually drops to a small fraction of the peak obtained.

The  $J_{IC}$  test procedure is usually performed using compact-tension specimens, although three-point bend specimens are also possible provided care is taken to ensure that accurate instrumentation is available to measure load-line displace-

**Fig. 13** Example of an  $R$  curve from a  $J_{Ic}$  fracture toughness test performed on a high-strength weld.

ment. The primary challenge with  $J_{Ic}$  testing is the high accuracy required from measurements of the load-line displacement. High-resolution measurement is required so as to infer the extremely small amount of crack tearing necessary for the  $J_{Ic}$  fracture toughness definition. This high accuracy is practically achieved through higher accuracy (minimum of 16 bit), low noise data acquisition boards combined with extreme care and control over the critical test details, especially as related to loading pin interfaces and clip gauge attachment.

In editions of the ASTM test standards prior to 1998, the test method for the elastic-plastic  $J_{Ic}$  parameter has always been described in ASTM E813. However, the E08 committee of ASTM has recently published a combined approach under the designation E1820. This combined approach outlines a procedure to follow that can result in any one of the primary toughness parameters, namely  $K_{Ic}$ ,  $K$ -, and  $J$ -resistance curves. Although these three parameters constitute the most common fracture test standards, other ASTM methods are also available:

- Crack-tip opening displacement (CTOD) fracture toughness (E1290)
- Plane-strain crack arrest fracture toughness (E1221)
- Fracture testing with surface-crack tension specimens (E740)
- Chevron notch fracture toughness of metallic materials (E1304)

However, these methods are typically not as wide-ranging nor as commonly encountered in design as the previously noted fracture toughness test methods.

## 6 FATIGUE TESTING

The previous section described basic fracture mechanics concepts as well as the test methods used to quantify fracture behavior given a preexisting crack. In this

section the process of crack nucleation (e.g., crack initiation) and stable propagation (e.g., crack growth) under cyclic loading is addressed. Understanding crack propagation behavior is critically important since some structures, most notably the current fleet of commercial airliners, adopt a damage tolerance design philosophy whereby cracks are assumed in the structure, and a safe structural life requires detecting and managing these cracks. Quantifying crack nucleation is also important since much of a crack's cyclic life is spent initiating or growing when it is small in size.

The test specimens used for fatigue crack initiation testing are similar geometrically to tensile specimens. The two basic test methods for initiation testing are ASTM E606 and E466 for strain- and stress-controlled testing, respectively. With both of these methods, the goal is to cycle a specimen until failure occurs. Strain control is typically used if (a) the loading is with a constant displacement or (b) the focus is on the short life regime (estimated to be less than  $10^3$  to  $10^5$  cycles although this is fairly controversial) where applied stress levels often approach the yield strength of the metallic material. Conversely load control testing is performed for the mid- to high-cycle life regime. Stress (effectively load) control testing is relatively straightforward since no displacement monitoring or measurement is required. The specimen can be gripped, cycling can commence, and continue unmonitored (provided the servocontrol loop does not require any attention) until failure occurs.

One of the most critical details when performing this type of fatigue testing is controlling bending in the specimen. Poor control of bending typically increases the apparent scatter in the fatigue data generated. Commercial alignment fixtures are available to mitigate bending. These fixtures utilize a strain gauged specimen and a fixture that allows minute adjustments of the loading train. However, these fixtures are not always available, which means less high tech and pragmatic methods are often required to minimize the effect.

Although guidelines on how to measure and verify specimen alignment are provided in ASTM E1012, minimizing bending practically requires control of three issues. First, the specimen must be carefully machined with excellent dimensional control, parallelism, and axisymmetry. Second, the fixtures used to connect the specimen to the loading train must not introduce any asymmetry. Threaded specimen ends, although commonly employed during fatigue testing, should be avoided as the tolerances required to engage the thread make accurate alignment problematic (however, it must be stated that it is not always practical or possible to avoid threaded ends). If the loading cycle is tensile only (e.g., a positive  $R$  ratio where  $R$  is the ratio of minimum to maximum load), a spherical joint, or more commonly known as a U-joint, in the loading train can minimize bending. Third, the fixtures in the load train should be designed well enough to grip repeatably in the same manner so that once a load train has been carefully aligned with an instrumented specimen it does not vary.

Some typical stress-life ( $S-N$ ) data are shown in Fig. 14 for two materials, an aluminum and titanium alloy.  $S-N$  data are usually generated at a fixed  $R$  ratio with the results represented as a plot with stress amplitude or maximum stress on the abscissa and cyclic life on the ordinate. Data are sometimes generated on specimens that have a groove or hole to simulate stress concentrations typically found in structure. Furthermore, it is often of practical interest to know

**Fig. 14** Conventional S-N fatigue test data presented for example titanium and aluminum alloy materials.

the endurance limit of a metallic material; in theory the endurance limit is defined as the applied stress level that corresponds to infinite life, in practical terms infinite life is approximated in the laboratory as a million cycles. The usual approach<sup>8</sup> is to test 30 specimens using an iterative, staircase method to converge on the stress level corresponding to the endurance limit. The nominal stress step chosen is approximately 2% of the ultimate tensile strength of the metallic material. Although this is a test-intensive methodology, the technique is able to clearly define the endurance limit to the accuracy given by the stress step.

The specimens used for fatigue crack propagation testing are similar to that described previously when discussing fracture. The most common geometries are the compact tension, C(T), and the middle cracked tension, M(T), specimens. However the pin-loaded C(T) is most suitable for positive  $R$  ratio (e.g., tension) since the cracked geometry is unstable in compression. Fatigue crack growth (FCG) testing is described in detail in one of the longest and most complex ASTM test standards, ASTM E647. The standard has grown in length as the understanding of the fatigue crack growth process has deepened. During FCG testing the goal is to determine crack growth rate as a function of stress intensity factor range,  $\Delta K$ . A typical series of fatigue crack growth curves are shown in Fig. 15 for an aluminum alloy subject to a number of different stress ratios. The central regions of the crack growth curves can be observed to be relatively linear as expected in the moderate growth rate Paris regime.

One of the most critical aspects of fatigue crack growth testing is measurement of the crack length. The most common method is to use a traveling tele-microscope mounted on a vernier scale for accurate measurement. Recent advances in both crack length measurement and test automation<sup>9,10</sup> employ elas-

**Fig. 15** Series of fatigue crack growth curves for aluminum at various  $R$  ratios.

tic compliance and electric potential drop methods to measure crack length. However, it is critical to note that these indirect, nonabsolute measurement techniques both require periodic visual crack length measurement for each test to ensure proper calibration. The quality of a laboratory's nonvisual crack length measurement technique and equipment is critical and often directly related to the quality of the FCG data generated.

The conventional method for performing crack growth testing is to record growth rate data with a fixed loading cycle as the crack grows. More efficient, newer methods are now available that critically depend upon nonvisual crack length measurement methods to control the applied loading. For instance,  $K$  gradient techniques can be used where the quantity  $C = dK/K da$  is fixed at different levels for different portions of the test. This increases efficiency since (a) it allows the generation of multiple crack growth data sets from the same specimen and (b) data can be generated in short growth intervals resulting in much faster data generation than with constant amplitude loading. However, these advanced fatigue crack growth test techniques must be carefully applied by experienced testing professionals who fully understand the limitations of this accelerated approach and have the instrumentation available to accurately measure crack length nonvisually.

Most fatigue crack growth rate testing is performed at a fixed load ratio since this variable does not change for many structures. However, another method

gaining wide popularity is generating FCG data from the highest rates down to near threshold (e.g., crack growth rate at a very low magnitude, a quantity especially useful for design purposes) using a constant  $K_{max}$ , increasing  $K_{min}$  loading condition. Consequently when the test starts, the  $R$  ratio is low (0.1 or so) and as the test progresses  $R$  increases until approximately 0.9 or more in the near-threshold regime. Whereas conventional fatigue crack growth threshold testing may take weeks or months to complete, this method results in a highly accelerated test and can be performed in a matter of days. Again, care must be taken to ensure that the choice of the variable test control parameters does not affect the magnitudes or trends of the fatigue crack growth rate data obtained.

For design purposes, it is sometimes necessary to understand the potential impact of external variables on FCG behavior. For this case, constant  $\Delta K$  testing can be employed to determine effects difficult and time consuming to detect if a complete crack growth curve were generated. As observed in the data in Fig. 16, several regions of nominally constant  $\Delta K$  are sequentially applied with the external environmental variable perturbed for each segment. This allows a better assessment of the effect of the variable since a statistically relevant number of crack growth rates are available for each segment. Although this is a highly

**Fig. 16** Influence of environment on fatigue crack growth rate behavior using a constant  $\Delta K$  testing approach.

efficient method to determine effects, the disadvantage is that the measurement strictly applies to only one constant  $\Delta K$  level. Nevertheless, a similar approach can be used to indirectly determine, for instance, the magnitude of internal residual stresses in a component by examining small changes in fatigue crack growth rate.

The challenge in applying fatigue crack growth rate data is accounting for the variable amplitude loading environment typically applied to a component in service. Most of the analytical tools available are empirically based and require some testing under the variable amplitude, spectrum load condition. In these cases, it is not uncommon to perform a crack growth test using a repeated variable amplitude spectrum derived from either service recorded or design loading. The test specimens in these cases are typically more complex, reflecting some design detail such as a fastener hole or weld. Rather than generating crack growth rate data with these tests, the goal is typically to provide crack length as a function of spectrum passes (or cycle count). Although this type of test is widely performed in the aerospace and ground vehicle industries,<sup>11</sup> the myriad of approaches used has stifled standardization, and it is only now underway within ASTM to develop a standard practice applicable to this highly complex test.

## 7 OTHER MECHANICAL TESTING

There are a number of test methods and procedures that are related to the areas described earlier but, in the spirit of brevity, have been omitted. Nevertheless, several are sufficiently popular and warrant some mention, albeit brief.

Some highly specialized assessments other than tensile tests exist for determining the strength and ductility of a metallic material. One common application for the bending strength test is the use of flat metallic materials for spring applications (ASTM E855). The two primary properties that this test provides are the modulus of elasticity in bending and the bending yield strength (proportional limit). Moreover bend tests used to assess ductility (ASTM E190 and E290) do not provide quantitative results, but rather provide a deformed sample suitable for close visual inspection to determine basic metallic material behavior. The region of highest strain is typically inspected for possible cracking, rumples, or orange peeling as a quality control assessment suitable for the shop floor.

High strain rate testing is another area where significant effort has been expended to generate the constituent properties applicable in the high rate regime. For instance, the split Hopkinson pressure bar deforms a sample at a high strain rate ( $>100\%$ ) while applying uniaxial stress to the sample. Similar methods have been developed that also allow high rate torsional loading. These methods have been successfully applied to a wide range of metallic materials.

Finally, numerous test techniques are also available for testing adhesion, friction, and wear of surfaces. These are critical issues from a design viewpoint with new standardized methods being developed fairly regularly.

## 8 ENVIRONMENTAL CONSIDERATIONS

It is often necessary to perform mechanical testing under environmental conditions other than ambient air. For instance, fatigue crack growth testing is often performed in either dry, high humidity, or aqueous conditions. For aqueous con-

**Fig. 17** Chamber around a flat panel M(T) specimen for suspending jet fuel or other aqueous environments while measuring fatigue crack growth rate behavior.

ditions, a setup as shown in Fig. 17 can be constructed to perform crack growth rate measurements. Sealing against a flat surface is relatively straightforward provided the materials used in the chamber are impervious to the environment contained.

Other strategies such as that shown in Fig. 18 can be used to seal the loading pins in a compact tension specimen. This technique has proven very suitable in the past for containing aqueous environments. Clear Teflon (PTFE) bags are commercially available that allow the setup to also be subjected to temperatures in the range of  $-400$  to  $300^{\circ}\text{F}$ . Simpler methods using supermarket polypropylene bags can also be used to contain conditioned air by introducing either desiccant or a hydrated sponge for the dry and humid conditions, respectively. Although the engineer's inclination might be to build a more elaborate environmental chamber, a simple plastic bag with duct tape seals works sufficiently well

**Fig. 18** Schematic of a compact tension specimen sealed with a plastic bag.

**Fig. 19** Several examples of enclosures for both high- and low-temperature materials testing. (Photos courtesy of the Instron Corporation and MTS Corporation)

to contain dry [ $<5\%$  relative humidity (RH)] and humid ( $>95\%$  RH) environments.

Finally, it is sometimes not simple to superimpose two rate-dependent processes without special attention. For instance, care must be taken to ensure that the time-dependent effects that often occur in an environment are properly applied in the materials test. As an example, the deleterious effect of seawater is gradually lost during a fatigue crack growth test as the frequency exceeds 1 Hz.

If a geometry is somewhat unusual and a setup does not fit into existing furnaces, it is sometimes necessary to construct a custom furnace from insulating fiberboard so long as the temperature required is not too high. In this case, a circulating fan is included along with a heater element and inexpensive temperature controller. However, an inexpensive approach such as the one just described will not perform well given an aggressive environment, higher pressure applications or more highly elevated temperatures. For these cases, more expensive and custom containments are typically required as shown in Fig. 19.

Thermomechanical fatigue (TMF) differs from the fatigue testing described earlier since the temperature of the specimen is programmed to vary in a precise manner relative to the mechanical loading. The challenge with this type of testing includes (a) achieving and (b) controlling the thermal environment required. The limiting factor is not usually with heating as induction furnaces, for instance, can heat a sample very rapidly in a uniform manner. The cycling rate is typically controlled by cooling and concerns regarding large thermal gradients exist if cooling occurs too quickly. Recent work within ASTM has generated a draft standard for TMF testing that is currently undergoing balloting.

## Acknowledgments

The author would like to graciously acknowledge the wisdom and lessons gained from working closely with two highly experienced colleagues and mentors at Southwest Research Institute. Jack FitzGerald taught me that often the simplest approach, the one that seemed too elementary and often at odds with engineering education, was always the best approach when faced with something unusual or

unknown in the laboratory. Furthermore, Andy Nagy exhibited incredible creativity by taking half-baked, malformed ideas and transforming them into real devices that functioned flawlessly in the test lab. Both of these consummate professionals, now deceased, provided excellent role models and mentors for the development of an inexperienced test engineer. Finally, gratitude is extended to FTA Inc, Instron, and MTS for supplying some of the photographs used herein.

Not too long ago, the concept of testing was merely an afterthought of the procurement process. But now, with the advent of science and technology, the concept of testing is an integral part of research and development, product design, and manufacturing. The question that is often asked is “why test?” The answer is simple. Times have changed. The manner in which we do things today is different. The emphasis is on automation, high production, and cost reduction. There is a growing demand for intricately shaped, high-tolerance parts. Consumer awareness, a subject totally ignored by the manufacturers once upon a time, is now a major area of concern. Along with the requirements, our priorities have also changed. While designing a machine or a product, the first order of priority in most cases is safety and health. Manufacturers and suppliers are now required to meet a variety of standards and specifications. Obviously, relying merely on past experience and quality of workmanship is simply not enough. The following are some of the major reasons for testing:

1. To prove design concepts
2. To provide a basis for reliability
3. Safety

4. Protection against product liability suits
5. Quality control
6. To meet standards and specifications
7. To verify the manufacturing process
8. To evaluate competitors' products
9. To establish a history for new materials

In the last two decades, just about every manufacturer has turned to plastics to achieve cost reduction, automation, and high yield. The lack of history along with the explosive growth and diversity of polymeric materials has forced the plastics industry into placing extra emphasis on testing and developing a wide variety of testing procedures. Through the painstaking efforts of various standards organizations, material suppliers, and mainly the numerous committees of the American Society for Testing and Materials (ASTM), over 10,000 different test methods have been developed.

The need for developing standard test methods specifically designed for plastic materials originated for two main reasons. Initially, the properties of plastic materials were determined by duplicating the test methods developed for testing metals and other similar materials. The Izod impact test, for example, was derived from the manual for testing metals. Because of the drastically different nature of plastic materials, the test methods often had to be modified. As a result, a large number of nonstandard tests were written by various parties. As many as 8–10 distinct and separate test methods were written to determine the same property. Such practice created total chaos among the developers of the raw materials, suppliers, design engineers, and ultimate end users. It became increasingly difficult to keep up with various test methods as well as to comprehend the real meaning of reported test values. The standardization of test methods acceptable to everyone solved the problem of communication between developers, designers, and end users, allowing them to speak a common language when comparing the test data and results.

In spite of the standardization of various test methods, we still face the problem of comprehension and interpretation of the test data by an average person in the plastics industry. This is due to the complex nature of the test procedures and the number of tests and testing organizations. The key in overcoming this problem is to develop a thorough understanding of what the various tests mean and the significance of the result to the application being considered. Unfortunately, the plastics industry has placed more emphasis on *how* and not enough on *why*, which obviously is more important from the standpoint of comprehension of the test results and understanding the true meaning of the values. The lack of understanding of the real meaning of heat deflection temperature, which is often interpreted as the temperature at which a plastic material will sustain static or dynamic load for a long period, is one such classic example of misinterpretation. In the chapters to follow, we concentrate on the significance, interpretation, and limitations of physical property data and test procedures. Finally, a word of caution: It is extremely important to understand that the majority of physical property tests are subject to rather large errors. As a general rule, the error of testing should be considered  $\pm 5\%$ . Some tests are more precise than others. Such testing errors come about from three major areas: one from the

basic test itself, the second from the operators conducting the tests, and the third from the variations in the test specimens. While evaluating the test data and making decisions based on test data, one must consider the error factor to make certain that a valid difference in the test data exists.

## 1 MECHANICAL PROPERTIES

The mechanical properties, among all the properties of plastic materials, are often the most important properties because virtually all service conditions and the majority of end-use applications involve some degree of mechanical loading. Nevertheless, these properties are the least understood by most design engineers. The material selection for a variety of applications is quite often based on mechanical properties such as tensile strength, modulus, elongation, and impact strength. These values are normally derived from the technical literature provided by material suppliers. More often than not, too much emphasis is placed on comparing the published values of different types and grades of plastics and not enough on determining the true meaning of the mechanical properties and their relation to end-use requirements. In practical applications, plastics are seldom, if ever, subjected to a single, steady deformation without the presence of other adverse factors such as environment and temperature. Since the published values of the mechanical properties of plastics are generated from tests conducted in a laboratory under standard test conditions, the danger of selecting and specifying a material from these values is obvious. A thorough understanding of mechanical properties, tests employed to determine such properties, and the effect of adverse conditions on mechanical properties over a long period is extremely important.

### 1.1 Tensile Tests (ASTM D638, ISO 527-1)

Tensile elongation and tensile modulus measurements are among the most important indications of strength in a material and are the most widely specified properties of plastic materials. Tensile test, in a broad sense, is a measurement of the ability of a material to withstand forces that tend to pull it apart and to determine to what extent the material stretches before breaking. Tensile modulus, an indication of the relative stiffness of a material, can be determined from a stress–strain diagram. Different types of plastic materials are often compared on the basis of tensile strength, elongation, and tensile modulus data. Many plastics are very sensitive to the rate of straining and environmental conditions. Therefore, the data obtained by this method cannot be considered valid for applications involving load-time scales or environments widely different from this method. The tensile property data are more useful in preferential selection of a particular type of plastic from a large group of plastic materials and such data are of limited use in actual design of the product. This is because the test does not take into account the time-dependent behavior of plastic materials.

The tensile testing machine of a constant-rate-of-crosshead movement is used. It has a fixed or essentially stationary member, carrying one grip and a movable member carrying a second grip. Self-aligning grips employed for holding the test specimen between the fixed member and the movable member prevent alignment problems. A controlled velocity drive mechanism is used. Some of the commercially available machines use a closed-loop servo-controlled drive mechanism to provide a high degree of speed accuracy. A load-indicating mechanism

capable of indicating total tensile load with an accuracy of  $\pm 1\%$  of the indicated value or better is used. Lately, the inclination is toward using digital-type load indicators, which are easier to read than the analog-type indicators. An extension indicator, commonly known as the extensometer, is used to determine the distance between two designated points located within the gauge length of the test specimen as the specimen is stretched. Figure 1 shows a commercially available tensile testing machine. The advent of new microprocessor technology has virtually eliminated time-consuming manual calculations. Stress, elongation, modulus, energy, and statistical calculations are performed automatically and presented on a visual display or hard-copy printout at the end of the test.

## 1.2 Flexural Properties (ASTM D790, ISO 178)

The stress-strain behavior of polymers in flexure is of interest to a designer as well as a polymer manufacturer. Flexural strength is the ability of the material to withstand bending forces applied perpendicular to its longitudinal axis. The stresses induced due to the flexural load are a combination of compressive and tensile stresses. This effect is illustrated in Fig. 2. Flexural properties are reported and calculated in terms of the maximum stress and strain that occur at the outside surface of the test bar. Many polymers do not break under flexure even after a large deflection that makes determination of the ultimate flexural strength impractical for many polymers. In such cases, the common practice is to report flexural yield strength when the maximum strain in the outer fiber of the specimen has reached 5%. For polymeric materials that break easily under flexural load, the specimen is deflected until a rupture occurs in the outer fibers.

There are several advantages of flexural strength tests over tensile tests. If a material is used in the form of a beam and if the service failure occurs in bending, then a flexural test is more relevant for design or specification purposes than a tensile test, which may give a strength value very different from the calculated strength of the outer fiber in the bent beam. The flexural specimen is comparatively easy to prepare without residual strain. The specimen alignment is also more difficult in tensile tests. Also, the tight clamping of the test specimens creates stress concentration points. One other advantage of the flexural test is that at small strains, the actual deformations are sufficiently large to be measured accurately.

There are two basic methods that cover the determination of flexural properties of plastics. Method 1 is a three-point loading system utilizing center loading on a simple supported beam. A bar of rectangular cross section rests on two supports and is loaded by means of a loading nose midway between the supports. The maximum axial fiber stresses occur on a line under the loading nose. A closeup of a specimen in the testing apparatus is shown in Fig. 3. This method is especially useful in determining flexural properties for quality control and specification purposes.

Method 2 is a four-point loading system utilizing two load points equally spaced from their adjacent support points, with a distance between load points of one-third of the support span. In this method, the test bar rests on two supports and is loaded at two points (by means of two loading noses), each an equal distance from the adjacent support point. Method 2 is very useful in testing materials that do not fail at the point of maximum stress under a three-point

**Fig. 1** Tensile testing machine. (Courtesy Tinius Olsen Corporation)

**Fig. 3** Close-up of a specimen shown in flexural testing apparatus.  
(Courtesy DuPont Company)

loading system. The maximum axial fiber stress occurs on a line under the loading nose.

Either method can be used with the two procedures. Procedure A is designed principally for materials that break at comparatively small deflections. Procedure B is designed particularly for those materials that undergo large deflections during testing. The basic difference between the two procedures is the strain rate, procedure A being 0.01 in./in./min, and procedure B being 0.10 in./in./min.

### **Modulus of Elasticity (Flexural Modulus)**

The flexural modulus is a measure of the stiffness during the first or initial part of the bending process. This value of the flexural modulus is, in many cases, equal to the tensile modulus.

The flexural modulus is represented by the slope of the initial straight-line portion of the stress-strain curve and is calculated by dividing the change in stress by the corresponding change in strain.

### 1.3 Creep Properties

Today, plastics are used in applications that demand high performance and extreme reliability. Many components, conventionally made of metals, are now made of plastics. The pressure is put on the design engineer to design the plastic products more efficiently. An increasing number of designers have now recognized the importance of thoroughly understanding the behavior of plastics under long-term load and varying temperatures. Such behavior is described in terms of creep properties.

When a plastic material is subjected to a constant load, it deforms quickly to a strain roughly predicted by its stress-strain modulus, and then continues to deform slowly with time indefinitely or until rupture or yielding causes failure. This phenomenon of deformation under load with time is called creep. All plastics creep to a certain extent. The degree of creep depends upon several factors, such as type of plastic, amount of load, temperature, and time.

The short-term stress-strain data is of little practical value in actual designing the part, since such data does not take into account the effect of long-term loading on plastics. Creep behavior varies considerably among types of plastics; however, under proper stress and temperature conditions, all plastics will exhibit a characteristic type of creep behavior. One such generalized creep curve is shown in Fig. 4. The total creep curve is divided into four continuous stages.

Fig. 4 Generalized creep curve

The first stage (OP) represents the instantaneous elastic deformation. This initial strain is the sum of the elastic and plastic strain. The first stage is followed by the second stage (PQ) in which strain occurs rapidly but at a decreasing rate. This stage, where creep rate decreases with time, is sometimes referred to as creep or primary creep. The straight portion of the curve (QR) is characterized by a constant rate of creep. This process is called “cold flow.” The final stage (RS) is marked by increase in creep rate until the creep fracture occurs.

If the applied load is released before the creep rupture occurs, an immediate elastic recovery, substantially equal to elastic deformation followed by a period of slow recovery is observed. The material in most cases does not recover to the original shape and a permanent set remains. The magnitude of the permanent set depends upon length of time, amount of stress applied, and temperature.

The creep values are obtained by applying constant load to the test specimen in tension, compression, or flexure and measuring the deformation as a function of time. The values are most commonly referred to as tensile creep, compressive creep, and flexural creep.

### **Tensile Creep**

Tensile creep measurements are made by applying the constant load to a tensile test specimen and measuring its extension as a function of time. The extension measurement can be carried out several different ways. The simplest way is to make two gauge marks on the tensile specimen and measure the distance between the marks at specified time intervals. The percent creep strain is determined by dividing the extension by initial gauge length and multiplying by 100. The percent creep strain is plotted against time to obtain a tensile creep curve. The tensile stress values are also determined at specified time intervals to facilitate plotting a stress rupture curve. The more accurate measurements require the use of a strain gauge, which is capable of measuring and amplifying small changes in length with time and directly plotting them on a chart paper. Figure 5 illustrates a typical setup for tensile creep testing. The test is also carried out at different stress levels and temperatures to study their effect on tensile creep properties.

### **Flexural Creep**

Flexural creep measurements are also made by applying a constant load to the standard flexural test specimen and measuring its deflection as a function of time. A typical test setup for measuring creep in flexure is shown in Fig. 6. As illustrated, the deflection of the specimen at midspan is measured using a dial indicator gauge. The electrical resistance gauges may also be used in place of a dial indicator. The deflections of the specimen are measured at a predetermined time interval.

## **1.4 Stress Relaxation**

Stress relaxation is defined as a gradual decrease in stress with time, under a constant deformation (strain). This characteristic behavior of the polymers is studied by applying a fixed amount of deformation to a specimen and measuring the load required to maintain it as a function of time. This is in contrast to creep measurement, where a fixed amount of load is applied to a specimen and resulting deformation is measured as a function of time.

**Fig. 5** Typical test setup for tensile creep testing. (Courtesy Applied Test Systems Inc.)

**Fig. 6** Flexural creep testing. (Courtesy Ceast U.S.A. Inc.)

Stress relaxation behavior of the polymers has been overlooked by many design engineers and researchers, partly because the creep data is much easier to obtain and is readily available. However, many practical applications dictate the use of stress relaxation data. For example, extremely low-stress relaxation is desired in the case of a threaded bottle closure, which may be under constant strain for a long period. If the plastic material used in the closures shows an excessive decrease in stress under this constant deformation, the closures will eventually fail. Similar problems can be encountered with metal inserts in molded plastics, belleville or multiple cantilever springs used in cameras, appliances, and business machines.

Stress relaxation measurements can be carried out using a tensile testing machine such as that described earlier in this chapter. However, the use of such a machine is not always practical because the stress relaxation test ties up the machine for a long period of time. The equipment for a stress relaxation test must be capable of measuring very small elongation accurately, even when applied at high speeds. Many sophisticated pieces of equipment now employ a strain gauge or a differential transformer along with a chart recorder capable of plotting stress as a function of time. A typical stress–time curve is schematically plotted in Fig. 7. At the beginning of the experiment, the strain is applied to the specimen at a constant rate to achieve the desired elongation. Once the specimen reaches the desired elongation, the strain is held constant for a predetermined amount of time. The stress decay, which occurs due to stress relaxation, is observed as a function of time. If a chart recorder is not available, the stress values at different time intervals are recorded and the results are plotted to obtain a stress versus time curve. The stress relaxation experiment is often carried out at various levels of temperature and strain. The stress data obtained from the stress relaxation experiment can be converted to a more meaningful apparent modulus data by simply dividing stress at a particular time by the applied strain. The curve may be replotted to represent apparent modulus as a function of time. The use of logarithmic coordinates further simplifies the stress relaxation data by

Fig. 7 Stress–time curve. (Courtesy Instron Corporation)

allowing us to use standard extrapolation methods such as the one used in creep experiments.

### 1.5 Impact Properties

The impact properties of the polymeric materials are directly related to the overall toughness of the material. Toughness is defined as the ability of the polymer to absorb applied energy. The area under the stress–strain curve is directly proportional to the toughness of a material. Impact strength is a measure of toughness. The higher the impact strength of a material, the higher the toughness and vice versa. Impact resistance is the ability of a material to resist breaking under a shock loading or the ability to resist the fracture under stress applied at high speed.

The theory behind toughness and brittleness of the polymers is very complex and therefore difficult to understand. The molecular flexibility plays an important role in determining the relative brittleness or toughness of the material. For example, in stiff polymers such as polystyrene and acrylics, the molecular segments are unable to disentangle and respond to the rapid application of mechanical stress and the impact produces brittle failure. In contrast, flexible polymers such as plasticized vinyls have high-impact strength due to the ability of the large segments of molecules to disentangle and respond rapidly to mechanical stress.

Impact properties of the polymers are often modified simply by adding an impact modifier such as butadiene rubber or certain acrylic compounds. The addition of a plasticizer also improves the impact strength at the cost of rigidity. Material such as nylon, which has relatively fair impact strength, can be oriented by aligning the polymer chains to improve the impact strength substantially. Another way to improve the impact strength is to use fibrous fillers that appear to act as stress transfer agents.

Most polymers, when subjected to the impact loading, seem to fracture in a characteristic fashion. The crack is initiated on a polymer surface due to the impact loading. The energy to initiate such a crack is called the crack initiation energy. If the load exceeds the crack initiation energy, the crack continues to propagate. A complete failure occurs when the load has exceeded the crack propagation energy. Thus, both crack initiation and crack propagation contribute to the measured impact strength. There are basically four types of failures encountered due to the impact load.

**Brittle Fracture.** In this type of failure the part fractures extensively without yielding. A catastrophic mechanical failure such as the one in the case of general-purpose polystyrene is observed.

**Slight Cracking.** The part shows evidence of slight cracking and yielding without losing its shape or integrity.

**Yielding.** The part actually yields showing obvious deformation and stress whitening but no cracking takes place.

**Ductile Failure.** This type of failure is characterized by a definite yielding of material along with cracking. Polycarbonate is considered a ductile material.

The distinction between the four types of failures is not very clear and some overlapping is quite possible.

Impact strength is one of the most widely specified mechanical properties of the polymeric materials. However, it is also one of the least understood properties. Predicting the impact resistance of plastics still remains one of the most troublesome areas of product design. One of the problems with some earlier Izod and Charpy impact tests was that the tests were adopted by the plastic industry from metallurgists. The principles of impact mechanisms as applied to metals do not seem to work satisfactorily with plastics because of the plastics' complex structure.

### Types of Impact Tests

In the 1980s and 1990s, a tremendous amount of time and money have been spent on research and development of various types of impact tests by organizations throughout the world. Attempts have been made to develop different sizes and shapes of specimens as well as impact testers. The specimens have been subjected to a variety of impact loads including tensile, compression, bending, and torsion impacts. Impact load has been applied using everything from a hammer, punches, and pendulums to falling balls and bullets. Unfortunately, very little correlation exists, if any, between the types of tests developed so far. Numerous technical papers and articles have been written on the subject of the advantages of one method over the other. To this date, no industrywide consensus exists regarding an ideal impact test method. In this chapter, an attempt is made to discuss as many types of impact tests as possible along with the respective advantages and limitations of each test. Impact testing is divided into three major classes and subdivided into several classes as follows:

**Pendulum Impact Test: IZOD–CHARPY (ASTM D-256, ISO 179).** The objective of the Izod–Charpy impact test is to measure the relative susceptibility of a standard test specimen to the pendulum-type impact load. The results are expressed in terms of kinetic energy consumed by the pendulum in order to break the specimen. The energy required to break a standard specimen is actually the sum of energies needed to deform it, to initiate its fracture, and to propagate the fracture across it, and the energy expended in tossing the broken ends of the specimen. This is called the *toss factor*. The energy lost through the friction and vibration of the apparatus is minimal for all practical purposes and usually neglected.

The specimen used in Izod test must be notched. The reason for notching the specimen is to provide a stress concentration area that promotes a brittle rather than a ductile failure. A plastic deformation is prevented by such type of notch

in the specimen. The impact values are seriously affected because of the notch sensitivity of certain types of plastic materials.

The Izod test requires a specimen to be clamped vertically as a cantilever beam. The specimen is struck by a swing of a pendulum released from a fixed distance from the specimen clamp. A similar setup is used for the Charpy test except for the positioning of the specimen. In the Charpy method, the specimen is supported horizontally as a simple beam and fractured by a blow delivered in the middle by the pendulum. The obvious advantage of the Charpy test over the Izod test is that the specimen does not have to be clamped and, therefore, it is free of variations in clamping pressures.

*Apparatus and Test Specimens.* The testing machine consists of a heavy base with a vise for clamping the specimen in place during the test. In most cases, the vise is designed so that the specimen can be clamped vertically for the Izod test or positioned horizontally for the Charpy test without making any changes. A pendulum-type hammer with an antifriction bearing is used. Additional weights may be attached to the hammer for breaking tougher specimens. The pendulum is connected to a pointer and a dial mechanism that indicates the excess energy remaining in a pendulum after breaking the specimen. The dial is calibrated to read the impact values directly in in.-lb or ft.-lb. A hardened steel striking nose is attached to the pendulum. The Izod and Charpy tests use different types of striking noses. A detailed list of requirements is discussed in the ASTM standards book. Figure 8 illustrates a typical pendulum-type impact testing machine. The test specimens can be prepared either by molding or cutting them from a sheet. Izod test specimens are  $2\frac{1}{2} \times \frac{1}{2} \times \frac{1}{8}$  in. size. The most common specimen thickness is  $\frac{1}{8}$ -in. but  $\frac{1}{4}$  in. is preferred since it is less susceptible to bending and crushing. A notch is cut into a specimen very carefully by a milling machine or a lathe. The recommended notch depth is 0.100-in.

## Test Procedures

*Izod Test.* The test specimen is clamped into position so that the notched end of the specimen is facing the striking edge of the pendulum. The pendulum hammer is released, allowed to strike the specimen, and swing through. If the specimen does not break, more weights are attached to the hammer and the test is repeated until failure is observed. The impact values are read directly in in.-lbf or ft.-lbf from the scale. The impact strength is calculated by dividing the impact values obtained from the scale by the thickness of the specimen. For example, if a reading of 2 ft.-lbf is obtained using an  $\frac{1}{8}$ -in.-thick specimen, the impact value would be 16 ft.-lbf/in. of notch. The impact values are always calculated on the basis of 1-in.-thick specimens even though much thinner specimens are usually used. The reversed notched impact strength is obtained by reversing the position of a notched specimen in the vise. In this case, the notch is subjected to compressive rather than tensile stresses during impact. As discussed earlier in this chapter, the energy required to break a specimen is the sum of the energies needed to deform it, initiate and propagate the fracture, and toss the broken end (toss factor).

*Falling-Weight Impact Test.* The falling-weight impact test, also known as the drop impact test or the variable-height impact test, employs a falling weight. This falling weight may be a tup with a conical nose, a ball, or a ball-end dart.

**Fig. 8** Pendulum impact tester. (Courtesy Tinius Olsen Company)

The energy required to fail the specimen is measured by dropping a known weight from a known height onto a test specimen. The impact energy is normally expressed in ft-lb and is calculated by multiplying the weight of the projectile by the drop height.

The biggest advantage of the falling-weight impact test over the pendulum impact test or high-rate tension test is its ability to duplicate the multidirectional impact stresses that a part would be subjected to in actual service. The other obvious advantage is the flexibility to use specimens of different sizes and shapes, including an actual part. Unlike the notched Izod impact test, which measures the notch sensitivity of the material and not the material toughness, falling-weight impact tests introduce polyaxial stresses into the specimen and measure the toughness. The variations in the test results due to the fillers and reinforcements, clamping pressure, and material orientation are virtually eliminated in the falling-weight impact test. This type of test is also very suitable for determining the impact resistance of plastic films, sheets, and laminated materials.

Three basic ASTM tests are commonly used depending upon the application:

ASTM D5420. Impact resistance of flat rigid plastic specimen by means of a falling weight

ASTM D1709. Impact resistance of plastic film by the free-falling dart method

ASTM D2444. Test for impact resistance of thermo-plastic pipe and fittings by means of a tup

***Drop Impact Test.*** This falling-weight impact test is primarily designed to determine the relative ranking of materials according to the energy required to break flat rigid plastic specimens under various conditions of impact of a striker impacted by a falling weight. A free-falling weight, or a tup, is used to determine the impact resistance of the material.

Many different versions of test equipment exist today. They all basically operate on the same principle. Figure 9 illustrates one such typical commercially available testing machine. It consists of a cast aluminum base, a slotted vertical guide tube, a round-nose striker and striker holder, an 8-lb weight, a die and die

**Fig. 9** Drop impact tester. (Courtesy Byk-Gardner USA)

support, and a sample platform. The sample platform is used to position a sheet of desired thickness for impact testing. The die is removable from the base in order that the actual parts of complex shapes can be placed onto the base and impact tested.

The test is carried out by raising the weight to a desired height manually or automatically with the use of a motor-driven mechanism and allowing it to fall freely onto the other side of the striker. The striker transfers the impact energy to the flat test specimen positioned on a cylindrical die or a part lying on the base of the machine. The kinetic energy possessed by the falling weight at the instant of impact is equal to the energy used to raise the weight to the height of the drop and is the potential energy possessed by the weight as it is released. Since the potential energy is expressed as the product of weight and height, the guide tube can be marked with a linear scale representing the impact range of the instrument in in.-lb. Thus, the toughness or the impact resistance of a specimen or a part can be read directly off the calibrated scale in in.-lb. The energy loss due to the friction in the tube or due to the momentary acceleration of the punch is negligible.

An alternate method for achieving the same result utilizes an instrument that employs a free-falling dart dropped from a specified height onto a test specimen. The dart with a hemispherical head is constructed of smooth, polished aluminum or stainless steel. An electromagnetic, air-operated or other mechanical release mechanism with a centering device is used for releasing the dart. The dart is also fitted with a shaft long enough to accommodate removable incremental weights. A two-piece annular specimen clamp is used to hold the specimen.

***Instrumented Impact Testing.*** One of the biggest drawbacks of the conventional impact test methods is that it provides only one value—the total impact energy—and nothing else. The conventional tests cannot provide additional information on the ductility, dynamic toughness, fracture, and yield loads or the behavior of the specimen during the entire impact event.

This effectively limits the application of noninstrumented impact test methods to quality control and material ranking. Instrumented impact testers are generally suited for research and development as well as advance quality control.

Instrumented impact testers measure force continuously while the specimen is penetrated. The resulting data can be used to determine type of failure and maximum load, in addition to the amount of energy required to fracture the specimen. One of the most common type of failures occurring from ductile to brittle transition at low temperatures can only be observed by studying the load–energy–time curve. The fracture mode of a plastic is sensitive to the changes in temperature, and can change abruptly at or near the materials transition temperature. Manufacturers of plastic automotive components routinely test materials at low temperatures (–20 to –40°F) to assure that they will not become brittle in cold weather. By studying the shape of the load–time or load–deflection curve, the type of failure can be analyzed, and important information about its performance in service can be gathered. The new piezoelectric-equipped strikers offer increased sensitivity, opening the doors for testing a whole new range of materials. Applications involving light-weight products such as foam containers for eggs and ultra-thin films used in packaging industry can now be meaningfully tested.

All standard impact testers can be instrumented to provide a complete load and energy history of the specimen. Such a system monitors and precisely records the entire impact event, starting from the acceleration (from rest) to the initial impact and plastic bending to fracture initiation and propagation to the complete failure. The instrumentation is done by mounting the strain gauges or load cell onto the striking bit in the case of pendulum impact tester or onto the tup in the case of a drop impact tester. During the test, a fiber-optic device triggers an oscilloscope just before striking the specimen. The output of the strain gauge is recorded by the oscilloscope depicting the variation of the load applied to the specimen throughout the entire fracturing process. A complete load–time history of the entire specimen is obtained. The apparent total energy absorbed by the specimen can be calculated and plotted against time. The specimen displacement can be calculated by the double integration of the load–time curve and the load–displacement curve can be plotted. With the advent of microprocessor technology, some manufacturers are now capable of offering a unit that automatically calculates the sample displacement and provides a load–displacement curve eliminating the need for calculations. Many other useful data such as the impact rate, force and displacement at yield, and break, yield, and failure energies as well as modulus are calculated and printed out. A commercially available instrumented impact tester is shown in Fig. 10.

### Interpreting Impact Data

Modern instrumented impact test machines generate a complete record of (1) force applied to the specimen versus time, (2) displacement of the impactor

**Fig. 10** Instrumented impact tester. (Courtesy Instron Corporation)

(from the point of specimen contact) versus time, (3) velocity of the impactor versus time, and (4) energy absorbed by the specimen versus time.

When plotted (Fig. 11), many details of the impact event become clearly visible in the data. Most systems also analyze the data and provide tabulated reports of critical values. Results of instrumented impact tests are interpreted differently depending on the type of material being tested and the failure criteria applied.

For homogeneous materials, four values are critical:

*Maximum (yield) load* is simply the highest point on the load–time curve. Often the point of maximum load corresponds to the onset of material damage or complete failure.

*Energy to maximum (yield) load* is the energy absorbed by the specimen up to the point of maximum load. When maximum load corresponds to failure, the energy to max load is the amount of energy the specimen can absorb before failing.

*Total energy* is the amount of energy the specimen absorbed during the complete test. This number may be the same as energy to maximum load when the specimen abruptly fails at the maximum load point.

*Deflection to maximum (yield) load* is the distance the impactor traveled from the point of impact to the point of maximum load. Figure 12 shows a typical test data.

**High-Speed Impact Tests (ASTM D3763, ISO 6603-2).** An ever-increasing demand for engineering plastics and the need for sophisticated and meaningful impact test methods for characterizing these materials have forced the industry into developing new high-speed impact tests. These tests not only provide the

Fig. 11 Load–energy–time curve showing effect of impact on a specimen.

Fig. 12 Typical test data obtained with instrumented impact tester.  
(Courtesy Instron Corporation)

basic information regarding the toughness of the polymeric materials but also provide other important data of interest, such as the load–deflection curve and the total energy absorption. The high-speed impact test overcomes the basic limitations of conventional impact testing methods as discussed previously. The rate of impact can be varied from 30 to 570,000 in./min.

High-speed impact testing has gained considerable popularity in recent years because of its ability to simulate actual impact failures at high speeds. For example, conventional impact testing methods are useless in testing to meet advanced automotive crash standards that require the impact simulation at 28 mph (30,000 in./min). High-speed impact testers are able to meet the challenge. As discussed earlier in this chapter, almost all polymers are strain-rate sensitive. Two polymers, when impact tested at one strain rate, may show similar impact strength values. The same two polymers tested at a high strain rate show a completely different set of values.

Most versatile high-speed impact testing machine is capable of testing everything from the thin film that may require as low an impact rate as 30 in./min to the plastic automotive bumper that may require a high impact rate up to 30,000 in./min. The specimen or product can be tested under a controlled environment of temperature and humidity. The equipment basically consists of a tup attached to a motor wound spring or pneumatically powered actuator along with a plunger displacement measuring system. The force is detected with a fast responding quartz load cell mounted directly on the actuator. The velocity can be set digitally from 30 to 30,000 in./min. Some type of clamp assembly to hold the specimen in place is used. The equipment can also be fitted with an environmental chamber for specialized testing. The tester is equipped with a

CRT and  $x$ - $y$  plotter that automatically displays load versus displacement data. A built-in microprocessor provides more useful information, such as modulus, yield, and failure energies.

High-speed impact testers have been proven very useful in material evaluation. At low strain rates, some polymers fail in ductile manner. The same polymers appear to show brittle failure at high strain rates. The point at which this ductile-to-brittle transition takes place is of particular importance. A high-rate impact test can provide such information in a graphical form. Tests can also be carried out at different temperatures to find ductile–brittle transition points at various temperatures. Other useful applications of the high-speed impact tester include the process quality control, design evaluation, and assembly evaluation.

### **Abrasion Resistance Tests**

The material's ability to resist abrasion is most often measured by its loss in weight when abraded with an abraser. The most widely accepted abraser in the industry is called the Taber abraser. A variety of wheels with varying degree of abrasiveness is available. The grade of "calibrase" wheel designated CS-17 with 1000-g load seems to produce satisfactory results with almost all plastics. For softer materials less abrasive wheels with smaller load on the wheels may be used. The test specimen is usually a 4-in.-diameter disk or a 4-in.<sup>2</sup> plate having both surfaces substantially plane and parallel. A  $\frac{1}{2}$ -in.-diameter hole is drilled in the center. Specimens are conditioned employing standard conditioning practices prior to testing. To commence testing, the test specimen is placed on a revolving turntable. Suitable abrading wheels are placed on the specimen under certain set dead-weight loads. The turntable is started and an automatic counter records the number of revolutions. Most tests are carried out to at least 5000 revolutions. The specimens are weighed to the nearest milligram. The test results are reported as weight loss in mg/1000 cycles. The grade of abrasive wheel along with amount of load at which the test was carried out is always reported along with results.

Test methods such as ASTM D1044 (resistance of transparent plastic materials to abrasion) are also developed for estimating the resistance of transparent plastic materials to one kind of abrasion by measurement of its optical affects. The test is carried out in similar manner to that described above, except that 100 cycles with a 500-g load is normally used. A photoelectric photometer is used to measure the light scattered by abraded track. The percentage of the transmitted light that is diffused by the abraded specimens is reported as a test result.

Another method to study the resistance of plastic material to abrasion is by measuring the volume loss when a flat specimen is subjected to abrasion with loose abrasive or bonded abrasive on cloth or paper. This method is designated as ASTM D1242. Figure 13 illustrates a commercially available abrasion tester.

### **1.6 Fatigue Resistance**

The behavior of materials subjected to repeated cyclic loading in terms of flexing, stretching, compressing, or twisting is generally described as fatigue. Such repeated cyclic loading eventually constitutes a mechanical deterioration and progressive fracture that leads to complete failure. Fatigue life is defined as the

Fig. 13 Abrasion tester. (Courtesy Taber Industries)

number of cycles of deformation required to bring about the failure of the test specimen under a given set of oscillating conditions.

The failures that occur from repeated application of stress or strain are well below the apparent ultimate strength of the material. Fatigue data are generally reported as the number of cycles to fail at a given maximum stress level. The fatigue endurance curve, which represents stress versus number of cycles to failure, also known as  $S-N$  curve, is generated by testing a multitude of specimens under cyclic stress, each one at different stress levels. At high-stress levels, materials tend to fail at relatively low numbers of cycles. At low stresses, the materials can be stressed cyclically for an indefinite number of times and the failure point is virtually impossible to establish. This limiting stress below which material will never fail is called the fatigue endurance limit. The fatigue endurance limit can also be defined as the stress at which the  $S-N$  curve becomes asymptotic to the horizontal (constant stress) line. For most polymers, the fatigue endurance limit is between 25 and 30% of the static tensile strength. The fatigue resistance data are of practical importance in the design of gears, tubing, hinges, parts on vibrating machinery, and pressure vessels under cyclic pressures.

Two basic types of tests have been developed to study the fatigue behavior of plastic materials:

1. Flexural fatigue test
2. Tensile fatigue test

### Flexural Fatigue Test (ASTM D671)

The ability of a material to resist deterioration from cyclic stress is measured in this test by using a fixed cantilever-type testing machine capable of producing

a constant amplitude of force on the test specimen each cycle. The main feature of a fatigue testing machine is an unbalanced, variable eccentric, mounted on a shaft that is rotated at a constant speed by a motor. This unbalanced movement of an eccentric produces alternating force. The specimen is held as a cantilever beam in a vice at one end and bent by a concentrated load applied through a yoke fastened to the opposite end. A counter is used to record the number of cycles along with a cutoff switch to stop the machine when the specimen fails. A typical commercially available fatigue testing machine is illustrated in Fig. 14. The test specimen of two different geometries are used. If machined specimens are used, care must be taken to eliminate all scratches and tool marks from the specimens. Molded specimen must be stress relieved before using.

The test is carried out by first determining the complementary mass and effective mass of the test specimen. The load required to produce the desired stress is calculated from these values. The number of cycles required to produce failure is determined. The test is repeated at varying stress levels. A curve of stress versus cycles to failure ( $S-N$  diagram) is plotted from the test results.

### Tensile Fatigue Test

Unlike the flexural fatigue test, which uses the constant deflection (strain) principle, the tensile fatigue test is conducted under constant-load (stress) conditions. The specimen is dumbbell-shaped, about 2 in. long with a cylindrical cross section.

The test is conducted by mounting both ends of the dumbbell specimen in the testing machine. The specimen is rotated between two spindles, and stress in the form of tension and compression is applied. The specimen is subjected to the number of cycles of stress specified or until fracture occurs.

Fig. 14 Flexural fatigue tester. (Courtesy Fatigue Dynamics, Inc.)

1.7 Hardness Tests

Hardness is defined as the resistance of a material to deformation, particularly permanent deformation, indentation, or scratching. Hardness is purely a relative term and should not be confused with wear and abrasion resistance of plastic materials. Polystyrene, for example, has a high Rockwell hardness value but a poor abrasion resistance. Hardness test can differentiate relative hardness of different grades of a particular plastic. However, it is not valid to compare hardness of various types of plastics entirely on the basis of one type of test, since elastic recovery along with hardness is involved. The test is further complicated by a phenomenon such as creep. Many tests have been devised to measure hardness. Since plastic materials vary considerably with respect to hardness, one type of hardness test is not applicable to cover the entire range of hardness properties encountered. Two of the most commonly used hardness tests for plastics are the Rockwell hardness test and the Durometer hardness test. Rockwell hardness is used for relatively hard plastics such as acetals, nylons, acrylics, and polystyrene. For softer materials such as flexible polyvinyl chloride (PVC), thermoplastic rubbers, and polyethylene, Durometer hardness is often used. The typical hardness values of some common plastic materials are listed for comparison in Table 1.

Rockwell Hardness (ASTM D785)

The Rockwell hardness test measures the net increase in depth impression as the load on an indenter is increased from a fixed minor load to a major load and then returned to a minor load. The hardness numbers derived are just numbers without units. Rockwell hardness numbers are always quoted with a scale symbol representing the indenter size, load, and dial scale used. The hardness scales in order of increasing hardness are *R*, *L*, *M*, *E*, and *K* scales. The higher the number in each scale, the harder the material. There is a slight overlap of hardness scales and, therefore, it is quite possible to obtain two different dial readings on different scales for the same material. For a specific type of material,

Table 1 Typical Hardness Values of Some Common Plastic Materials

| Plastic material                | Hardness |         |           |
|---------------------------------|----------|---------|-----------|
|                                 | Rockwell |         | Durometer |
|                                 | M        | R       | Shore D   |
| Acetal                          | 94       | 120     |           |
| Acrylic                         | 85–105   |         |           |
| Acrylonitrile butadiene styrene |          | 75–115  |           |
| Cellulosics                     |          | 30–125  |           |
| Polyphenylene oxide             | 80       | 120     |           |
| Nylon                           |          | 108–120 |           |
| Polycarbonate                   | 72       | 118     |           |
| High-density polyethylene       |          |         | 60–70     |
| Low-density polyethylene        |          |         | 40–50     |
| Polypropylene                   |          |         | 75–85     |
| Polystyrene (general purpose)   | 68–70    |         |           |
| Polyvinyl chloride (rigid)      |          | 115     |           |
| Polysulfone                     | 70       | 120     |           |

correlation in the overlapping regions is possible. However, due to differences in elasticity, creep, and shear characteristics between different plastics, a general correlation is not possible.

### **Durometer Hardness (ASTM D2240, ISO 868)**

The Durometer hardness test is mostly used for measuring the relative hardness of soft materials. The test method is based on the penetration of a specified indenter forced into the material under specified conditions.

The Durometer hardness tester consists of a pressure foot, an indenter, and an indicating device. The indenter is spring loaded and the point of the indenter protrudes through the hole in the base. The test specimens are at least  $\frac{1}{4}$ -in. thick and can be either molded or cut from a sheet. Several thin specimens may be piled to form a  $\frac{1}{4}$ -in.-thick specimen but one piece specimens are preferred. The poor contact between the thin specimens may cause results to vary considerably.

The test is carried out by first placing a specimen on a hard, flat surface. The pressure foot of the instrument is pressed onto the specimen, making sure that it is parallel to the surface of the specimen. The durometer hardness is read within 1 sec after the pressure foot is in firm contact with the specimen.

Two types of durometers are most commonly used—type A and type D. The basic difference between the two types is the shape and dimension of the indenter. The hardness numbers derived from either scale are just numbers without any units. Type A durometer is used with relatively soft material while type D durometer is used with slightly harder material.

## **2 THERMAL PROPERTIES**

Thermal properties of plastic materials are equally as important as mechanical properties. Unlike metals, plastics are extremely sensitive to changes in temperature. The mechanical, electrical, or chemical properties of plastics cannot be looked at without looking at the temperature at which the values were derived. Crystallinity has a number of important effects upon the thermal properties of a polymer. Its most general effects are the introduction of a sharp melting point and the stiffening of thermal mechanical properties. Amorphous plastics, in contrast, have a gradual softening range. Molecular orientation also has a significant effect on thermal properties. Orientation tends to decrease dimensional stability at higher temperatures. The molecular weight of the polymer affects the low-temperature flexibility and low-temperature brittleness. Many other factors such as intermolecular bonding, cross-linking, and copolymerization all have a considerable effect on thermal properties. From the above discussion, it is very clear that the thermal behavior of polymeric materials is rather complex. Therefore, in designing a plastic part or selecting a plastic material from the available thermal property data, one must thoroughly understand the short-term as well as the long-term effect of temperature on properties of that plastic material.

### **2.1 Tests for Elevated Temperature Performance**

Designers and material selectors of plastic products constantly face the challenge of selecting a suitable plastic for elevated temperature performance. The difficulty arises due to the varying natures and capabilities of various types and grades of plastics at elevated temperatures. Many factors are considered when selecting a plastic for a high-temperature application. The material must be able

to support a design load under operating conditions without objectionable creep or distortion. The material must not degrade or lose necessary additives that will cause drastic reduction in the physical properties during the expected service life.

All the properties of plastic materials are not affected in a similar manner by elevating temperature. For example, electrical properties of a particular plastic may show only a moderate change at elevated temperatures, while the mechanical properties may be reduced significantly. Also, since the properties of plastic materials vary with temperature in an irregular fashion, they must be looked at as a function of temperature in order to obtain more meaningful information. From the foregoing, it is quite clear that a single maximum-use temperature that will apply to all the important properties in high-temperature applications is simply not possible.

One of the most important considerations while studying the performance of plastics at elevated temperatures is the dependence of key properties such as modulus, strength, chemical resistance, and environmental resistance on time. Therefore, the short-term heat resistance data alone is not adequate for designing and selecting materials that require long-term heat resistance. For the sake of convenience and simplicity, we divide the elevated temperature effects into two categories:

1. Short-term effects
  - a. Heat deflection temperature
  - b. Vicat softening temperature
  - c. Torsion pendulum
2. Long-term effects
  - a. Long-term heat resistance test
  - b. Underwriters Laboratory (UL) temperature index
  - c. Creep modulus/creep rupture tests

### Short-Term Effects

***Heat Deflection Temperature (HDT) (ASTM D648, ISO 75-1, ISO 75-2).*** Heat deflection temperature is defined as the temperature at which a standard test bar ( $5 \times \frac{1}{2} \times \frac{1}{4}$  in.) deflects 0.010 in. under a stated load of either 66 or 264 psi. The heat deflection temperature test, also referred to as the heat distortion temperature test, is commonly used for quality control and for screening and ranking materials for short-term heat resistance. The data obtained by this method cannot be used to predict the behavior of plastic materials at elevated temperature nor can it be used in designing a part or selecting and specifying material. Heat deflection temperature is a single-point measurement and does not indicate long-term heat resistance of plastic materials. Heat distortion temperature, however, does distinguish between those materials that lose their rigidity over a narrow temperature range and those that are able to sustain light loads at high temperatures.

The apparatus for measuring heat deflection temperature consists of an enclosed oil bath fitted with a heating chamber and automatic heating controls that raise the temperature of the heat transfer fluid at a uniform rate. A cooling

system is also incorporated to fast cool the heat transfer medium for conducting repeated tests. The specimens are supported on steel supports, 4 in. apart with the load applied on top of the specimen vertically and midway between the supports. The contact edges of the support and of the piece by which pressure is applied is rounded to a radius of  $\frac{1}{4}$  in. A suitable deflection measurement device, such as a dial indicator, is normally used. A mercury thermometer is used for measuring temperature. The unit is capable of applying 66 or 264 psi fiber stress on specimens by means of a dead weight. A commercially available heat deflection measuring device with a closeup of a specimen holder is illustrated in Fig. 15.

More recently, automatic heat deflection temperature testers have been developed. These testers typically replace conventional temperature and deflection measuring devices with more sophisticated electronic measuring devices with digital read-out system and a chart recorder that prints out the results. Such an automatic apparatus eliminates the need for the continuous presence of an operator and thereby minimizes operator-related errors.

The test specimens consist of test bars 5 in. in length,  $\frac{1}{2}$  in. in depth by any width from  $\frac{1}{8}$  to  $\frac{1}{2}$  in. The test bars may be molded or cut from extruded sheet as long as they have smooth, flat surfaces and are free from excessive sink marks or flash. The specimens are conditioned employing standard conditioning procedures.

The specimen is positioned in the apparatus along with the temperature and deflection measuring devices and the entire assembly is submerged into the oil bath kept at room temperature. The load is applied to a desired value (66 or 264 psi fiber stress). Five minutes after applying the load, the pointer is adjusted to zero and the oil is heated at the rate of  $2 \pm 0.2^{\circ}\text{C}/\text{min}$ . The temperature of the

**Fig. 15** DTUL/vicat tester. (Courtesy Atlas Electric Devices Company)

oil at which the bar has deflected 0.010 in. is recorded as the heat deflection temperature at the specified fiber stress.

### Long-Term Effects

The long-term effects of elevated temperature on properties of plastics are extremely important, especially when one considers the fact that the majority of applications involving high heat are long-term applications. During long-term exposure to heat, plastic materials may encounter many physical and chemical changes. A plastic material that shows little or no effect at elevated temperature for a short time may show a drastic reduction in physical properties, a complete loss of rigidity, and severe thermal degradation when exposed to elevated temperature for a long time. Along with time and temperature, many other factors such as ozone, oxygen, sunlight, and pollution combine to accelerate the attack on plastics. At elevated temperatures, many plastics tend to lose important additives such as plasticizers and stabilizers, causing plastics to become brittle or soft and sticky.

Three basic tests have been developed and accepted by the plastics industry. If the application does not require the product to be exposed to elevated temperature for a long period under continuous load, a simple heat resistance test is adequate. The applications requiring the product to be under continuous significant load must be looked at from creep modulus and creep rupture strength test data. Another one of the most widely accepted methods of measuring maximum continuous use temperature has been developed by Underwriters Laboratories. The UL temperature index, established for a variety of plastic materials to be used in electrical applications, is the maximum temperature that the material may be subjected to without fear of premature thermal degradation.

***Long-Term Heat Resistance Test (ASTM D794).*** The long-term heat resistance test was developed to determine the permanent effect of heat on any property by selection of an appropriate test method and specimen. In ASTM recommended practice, only the procedure for heat exposure is specified and not the test method or specimen.

Any specimen, including sheet, laminate, test bar, or molded part may be used. If a specific property, such as tensile strength loss is to be determined, a standard tensile test bar specimen and procedures must be used for comparison of test results before and after the test. The test requires the use of a mechanical convection oven with a specimen rack of suitable design to allow air circulation around the specimens. The test is carried out by simply placing the specimen in the oven at a desired exposure temperature for a predetermined length of time. The subsequent exposure to temperatures may be increased or decreased in steps of 25°C until a failure is observed. Failure due to heat is defined as a change in appearance, weight, dimension, or other properties that alter plastic material to a degree that it is no longer acceptable for the service in question. Failure may result from blistering, cracking, loss of plasticizer, or other volatile material that may cause embrittlement, shrinkage, or change in desirable electrical or mechanical properties.

Many factors that affect the reproducibility of the data. The degree of temperature control in the oven, the type of molding, cure, air velocity over the

specimen, period of exposure, and humidity of the oven room are some of these factors. The amount and type of volatiles in the molded part or specimen may also affect the reproducibility.

***UL Temperature Index.*** The increased use of plastic materials in electrical applications such as appliances, portable electrically operated tools and equipments, and enclosures has created a renewed interest in the ability of plastics to withstand mechanical abuse and high temperatures. A serious personal injury, electric shock, or fire may occur if the product does not perform its intended function. Underwriters Laboratories, an independent, not-for-profit organization concerned with consumer safety, has developed a temperature index to assist UL engineers in judging the acceptability of individual plastics in specific applications involving long-term exposure to elevated temperatures. The UL temperature index correlates numerically with the temperature rating or maximum temperature in degrees centigrade above which a material may degrade prematurely and therefore be unsafe.

***Relative Thermal Indices.*** The relative thermal index of a polymeric material is an indication of the material's ability to retain a particular property (physical, electrical, etc.) when exposed to elevated temperatures for an extended period of time. It is a measure of the material's thermal endurance. For each material, a number of relative thermal indices can be established, each index related to a specific thickness of the material.

The relative index of a material is determined by comparing the thermal-aging characteristic of one material of proven field service at a particular temperature level with the thermal-aging characteristics of another material with no field service history. A great deal of consideration is given to the properties that are evaluated to determine relative thermal index. For the relative thermal index to be valid, the properties being stressed in the end product must be included in the thermal-aging program. If, for any reason, the specific property under stress in the end product is not part of the long-term aging program, the relative thermal index may not be applicable to the use of the material in that particular application.

***Relative Thermal Index Based upon Historical Records.*** Through experience gained from testing a large volume of complete products and insulating systems over a long period, UL has established relative thermal indices on certain types of plastics. These fundamental temperature indices are applicable to each member of a generic material class. Table 2 lists the temperature indices based on past field test performance and chemical structure.

***Relative Thermal Index Based upon Long-Term Thermal Aging.*** The long-term thermal-aging program consists of exposing polymeric materials to heat for a predetermined length of time and observing the effect of thermal degradation. To carry out the testing, an electrically heated mechanical convection oven is preferred, however, with some provisions, a noncirculating static oven may be employed. The specific properties to be evaluated in the thermal-aging program are to be as nearly as possible representative of the properties required in the end application.

**Table 2 Relative Thermal Indices Based upon Past Field Test Performance and Chemical Structure<sup>a</sup>**

| Material                                        | Generic Thermal Index (°C) |
|-------------------------------------------------|----------------------------|
| Nylon (type 6, 11, 6/6, and 6/10) <sup>b</sup>  | 65                         |
| Polycarbonate <sup>b</sup>                      | 65                         |
| Molded phenolic <sup>c,d</sup>                  | 150                        |
| Molded melamine <sup>c,d</sup>                  | 130 <sup>c</sup>           |
| Molded melamine-phenolic <sup>c,d</sup>         | 130 <sup>c</sup>           |
| Fluorocarbon resins                             |                            |
| (1) Polytetrafluoroethylene                     | 150                        |
| (2) Polychlorotrifluoroethylene                 | 150                        |
| (3) Fluorinated ethylene propylene              | 150                        |
| Silicone rubber                                 | 105                        |
| Polyethylene terephthalate film                 | 105                        |
| Urea formaldehyde                               | 100                        |
| Molded alkyd <sup>c,d</sup>                     | 130                        |
| Molded epoxy <sup>c,d</sup>                     | 130                        |
| Molded diallyl phthalate <sup>c,d</sup>         | 130                        |
| Molded polyester <sup>c,d</sup> (thermosetting) | 130                        |

<sup>a</sup>From UL 746 B. Reprinted with permission from Underwriters Laboratories, Inc.

<sup>b</sup>Includes glass fiber-reinforced materials.

<sup>c</sup>Includes simultaneous heat and high-pressure matched metal die-molded compounds only. Excludes low-pressure or low-temperature curing processes such as open-mold (hand lay-up, spray-up, contact bag, filament winding), encapsulation, lamination, etc.

<sup>d</sup>Includes materials having filler systems of fibrous (other than synthetic organic) types but excludes fiber reinforcement systems using resins that are applied in liquid form.

<sup>e</sup>Compounds having a specific gravity of 1.55 or greater (including those having cellulosic filler material) are acceptable at temperatures not greater than 150°C (302°F).

The most common mechanical properties include tensile strength, flexural strength, and Izod impact strength. The electrical properties of concern are dielectric strength, surface or volume resistivity, arc resistance, and arc tracking. The test specimens are standard ASTM test bars, depending upon the type of test. The UL publication, “Polymeric Materials—Short-Term Property Evaluations, UL 746A,” describes the specimen and test procedures to determine mechanical and electrical properties.

To determine the relative thermal index, a control material with a record of good field service at its rated temperature is selected. The control material of the same generic type and the same thickness as the candidate material is preferred. At least four different oven temperatures are selected. The highest temperature is selected so that it will take no more than 2 months to produce end of life of the material. The next two lower temperatures must produce the anticipated end of life of 3 and 6 months, respectively. The lowest temperature selected will take 9 to 12 months for the anticipated results.

The end of life of a material is based upon the assumption that at least a 2:1 factor of safety exists in the applicable physical and electrical property re-

quirements. The end of life of a material is the time at each aging temperature, when a property value has decreased 50% of its unaged level. A 50% loss of property due to thermal degradation is not expected to result in premature, unsafe failure.

To avoid underrating the material's relative temperature index, UL publishes the ratings in three categories: applications involving electrical properties only, applications involving both electrical and mechanical properties, and applications involving both electrical and mechanical properties without impact resistance. UL publishes such data in its semiannual *Plastics Recognized Component Directory*. Since the long-term heat-aging resistance of plastics is dependent on the thickness of the part or test specimen, UL requires that the thermal index testing be carried out over a wide range of thicknesses. Finally, it is important to understand that the UL temperature index program recognizes that the upper temperature limits of plastics are dependent upon the stresses applied on the end product in use. Consequently, the temperature index of a particular plastic qualifies it only for those UL applications that UL has specifically approved.

## **2.2 Brittleness Temperature (ASTM D746, ISO 974)**

At low temperatures, all plastics tend to become rigid and brittle. This happens mainly because, at lower temperatures, the mobility of polymer chains is greatly reduced. In the case of the amorphous polymers, brittle failure occurs at a temperature well below glass transition temperature. The polymer tends to get tougher as it reaches glass transition temperature. By contrast, in crystalline polymers the toughness is mainly dependent on the degree of crystallinity, which generally creates molecular inflexibility resulting in only moderate impact strength. The size of the crystalline structure formed also has significant effect on the impact strength of the polymer. The larger the crystalline structure, the lower the impact strength. The polymers exhibiting ductile failure generally show high plastic deformation characterized by material stretching and tearing before fracturing. Brittleness temperature is defined as the temperature at which plastics and elastomers exhibit brittle failure under impact conditions. Yet another way to define brittleness temperature is the temperature at which 50% of the specimens tested exhibit brittle failure under specified impact conditions.

## **3 ELECTRICAL PROPERTIES**

The unbeatable combination of characteristics such as ease of fabrication, low cost, light weight, and excellent insulation properties have made plastics one of the most desirable materials for electrical applications. Although the majority of applications involving plastics are insulation related, plastics can be made to conduct electricity by simply modifying the base material with proper additives such as carbon black.

Until recently, plastics were considered a relatively weaker material in terms of load-bearing properties at elevated temperatures. Therefore, the use of plastics in electrical applications was limited to non-load-bearing, general-purpose applications. The advent of new high-performance engineering materials has altered the entire picture. Plastics are now specified in a majority of applications requiring resistance to extreme temperatures, chemicals, moisture, and stresses. The primary function of plastics in electrical applications has been that of an

insulator. This insulator or dielectric separates two field-carrying conductors. Such a function can be served equally well by air or vacuum. However, neither air nor vacuum can provide any mechanical support to the conductors. Plastics not only act as effective insulators but also provide mechanical support for field-carrying conductors. For this very reason, the mechanical properties of plastic materials used as insulators become very important. Typical electrical applications of plastic material include plastic-coated wires, terminals, connectors, industrial and household plugs, switches, and printed circuit boards.

The key electrical properties of interest are dielectric strength, dielectric constant, dissipation factor, volume and surface resistivity, and arc resistance.

### 3.1 Dielectric Strength (ASTM D149, IEC 243-1)

The dielectric strength of an insulating material is defined as the maximum voltage required to produce a dielectric breakdown. Dielectric strength is expressed in volts per unit of thickness such as V/mil. All insulators allow a small amount of current to leak through or around themselves. Only a perfect insulator, if there is such an insulator in existence, can be completely free from small current leakage. The small leakage generates heat, providing an easier access to more current. The process slowly accelerates with time and the amount of voltage applied until a failure in terms of dielectric breakdown or what is known as puncture occurs. Obviously, dielectric strength, which indicates electrical strength of a material as an insulator, is a very important characteristic of an insulating material. The higher the dielectric strength, the better the quality of an insulator. Three basic procedures have been developed to determine dielectric strength of an insulator. Figure 16 schematically illustrates the basic setup for a dielectric strength test. A variable transformer and a pair of electrodes are normally employed. Specimens of any desirable thickness prepared from the material to be tested are used. Specimen thickness of  $\frac{1}{16}$  in. is fairly common. The first procedure is known as the short-times method. In this method, the voltage is increased from zero to breakdown at a uniform rate. The rate of rise is gen-

Fig. 16 Schematic of dielectric strength test.

erally 100, 500, 1000, or 3000 V/s until the failure occurs. The failure is made evident by actual rupture or decomposition of the specimen. Sometimes a circuit breaker or other similar device is employed to signal the voltage breakdown. This is not considered a positive indication of voltage breakdown since other factors such as flashover, leakage current, corona current, or equipment magnetizing current can influence such indicating devices.

The second method is known as the slow-rate-of-rise method. The test is carried out by applying the initial voltage approximately equal to 50% of the breakdown voltage as determined by the short-time test or as specified. Next, the voltage is increased at a uniform rate until the breakdown occurs.

The step-by-step test method requires applying initial voltage equal to 50% of the breakdown voltage as determined by the short-time test and then increasing the voltage in equal increments and held for specified time periods until the specimen breaks down. In almost all cases the dielectric strength values obtained by step-by-step method corresponds better with actual use conditions. However, the service failures are generally at voltage below the rated dielectric strength because of the time factor involved.

## **3.2 Dielectric Constant and Dissipation Factor (ASTM D150, IEC 250)**

### **Dielectric Constant (Permittivity)**

Dielectric constant of an insulating material is defined as the ratio of the charge stored in an insulating material placed between two metallic plates to the charge that can be stored when the insulating material is replaced by air (or vacuum). Defined another way, the dielectric constant is the ratio of the capacitance by two metallic plates with an insulator placed between them and the capacitance of the same plates with a vacuum between them. Simply stated, the dielectric constant indicates the ability of an insulator to store electrical energy. In many applications, insulating materials are required to perform as capacitors. Such applications are best served by plastic materials having a high dielectric constant. Materials with a high dielectric constant have also helped in reducing the physical size of the capacitors. Furthermore, the thinner the insulating material, the higher the capacitance. Because of this fact plastic foils are extensively used in applications requiring high capacitance.

One of the main function of an insulator is to insulate the current-carrying conductors from each other and from the ground. If the insulator is used strictly for this purpose, it is desirable to have the capacitance of the insulating material as small as possible. For these applications, one is looking for the materials with very low dielectric constant.

The dielectric constant test is fairly simple. The test specimen is placed between the two electrodes, as shown in Fig. 17, and the capacitance is measured. Next, the test specimen is replaced by air and once again the capacitance value is measured. The dielectric constant value is determined from the ratio of the two measurements. Dielectric constant values are affected by factors such as frequency, voltage, temperature, humidity, etc.

### **Dissipation Factor**

In all electrical applications, it is desirable to keep the electrical losses to a minimum. Electrical losses indicate the inefficiency of an insulator. The dissi-

Dielectric constant is the ratio of the system capacitance with the plastic specimen as the dielectric to the capacitance with a vacuum as the dielectric.

**Fig. 17** Schematic of dielectric constant test. (Courtesy Bayer Corporation)

pation factor is a measure of such electrical inefficiency of the insulating material. The dissipation factor indicates the amount of energy dissipated by the insulating material when the voltage is applied to the circuit. The dissipation factor is defined as the ratio of the conductance of a capacitor in which the material is the dielectric to its susceptance or the ratio of its parallel reactance to its parallel resistance. Most plastics have a relatively lower dissipation factor at room temperature. However, at high temperatures, the dissipation factor is quite high, resulting in greater overall inefficiency in electrical system. Loss factor, which is the product of dielectric constant and the dissipation factor, is a frequently used term since it relates to the total loss of power occurring in insulating materials.

### 3.3 Electrical Resistance Tests

As stated earlier, the primary function of an insulator is to insulate current-carrying conductors from each other as well as from ground and to provide mechanical support for components. Naturally, the most desirable characteristic of an insulator is its ability to resist the leakage of the electrical current. The higher the insulation resistance, the better the insulator. Failure to recognize the importance of insulation resistance values while designing products such as appliances and power tools could lead to fire, electrical shock, and personal injury.

Insulation resistance can be subdivided into:

1. Volume resistance
2. Surface resistance

Volume resistance is defined as the ratio of the direct voltage applied to two electrodes that are in contact with a specimen to that portion of the current

between them that is distributed through the volume of the specimen. Or, simply stated, the volume resistance is the resistance to leakage through the body of the material. Volume resistance generally depends upon the material. The term most commonly used by designers is volume resistivity. It is defined as the ratio of the potential gradient parallel to the current in the material to the current density or, simply stated, the volume resistivity of a material is the electrical resistance between the opposite faces of a unit cube for a given material and at a given temperature.

High-volume resistivity materials are desirable in applications requiring superior insulating characteristics.

The surface resistance of a material is defined as the ratio of the direct voltage applied to the electrodes to that portion of the current between them that is primarily in a thin layer of moisture or other semiconducting material that may be deposited on the surface. Simply stated, surface resistance is the resistance to leakage along the surface of an insulator. The surface resistance of a material depends upon the quality and cleanliness of the surface of the product. A product with oil or dirt particles on it gives lower surface resistance values.

The test procedures to determine electrical resistance values are rather complex. ASTM D257 (IEC 93) describes the procedures as well as the complex electrodes and apparatus required to carry out the test in detail.

Temperature and humidity both seem to affect the insulation resistance appreciably. As a rule, the higher the temperature and humidity, the lower the insulation resistance of a material.

### **3.4 Arc Resistance (ASTM D495)**

Arc resistance is the ability of a plastic material to resist the action of a high-voltage electrical arc, usually stated in terms of time required to form material electrically conductive. Failure is characterized by carbonization of the surface, tracking, localized heating to incandescence, or burning. In all applications in which conducting elements are brought into contact, arcing is inevitable. Switches, circuit breakers, and automotive distributor caps are a few good examples of applications where arcing is known to cause failure. Another term that is generally associated with arcing is tracking. Tracking is defined as a phenomenon where a high-voltage source current creates a leakage or fault path across the surface of an insulating material by slowly but steadily forming a carbonized path appearing as a thin, wiry line between the electrodes. Tracking is accelerated by the presence of surface contaminants such as dirt and oil and by the presence of moisture. Resistance to arcing or tracking depends upon the type of plastic materials such as phenolics that tend to carbonize easily and therefore have relatively poor arc resistance. Plastics such as alkyds, melamines, and fluorocarbons are excellent arc-resistant materials. The failures due to arcing are not always because of carbonization or tracking. Many plastics such as acrylics simply do not carbonize. However, they do form ignitable gases that cause the product to fail in a short time. Arc resistance of plastics can be improved substantially by the addition of fillers such as glass, mineral, wood flour, asbestos, and other inorganic fillers. Table 3 lists the arc resistance of some common plastic materials.

The determination of the arc resistance of plastics using a standard test method has always been a problem because of the numerous ways the test can

**Table 3 Arc Resistance of Various Plastics**

| Plastics                                   | Arc Resistance<br>(sec) |
|--------------------------------------------|-------------------------|
| Polycarbonate (10–40 percent glass filled) | 5–120                   |
| Polycarbonate                              | 10–120                  |
| Polystyrene (high impact)                  | 20–100                  |
| ABS                                        | 50–85                   |
| Polystyrene (general purpose)              | 60–80                   |
| Rigid polyvinyl chloride                   | 60–80                   |
| Polysulfone                                | 75–190                  |
| Urea formaldehyde                          | 80–150                  |
| Ionomer                                    | 90–140                  |
| SAN                                        | 100–150                 |
| Epoxy                                      | 120–150                 |
| Acetal (homopolymer)                       | 130                     |
| Polyethylene (low-density)                 | 135–160                 |
| Polypropylene                              | 135–180                 |
| PTFE                                       | >200                    |
| Acrylics                                   | No track                |

be conducted. ASTM has developed four basic test methods to satisfy this concern. ASTM D495, which is high-voltage, low-current, dry arc resistance of solid electrical insulation, has been the most widely used and accepted. This test is only intended for the preliminary screening of materials, for detecting the effect of changes in formulations, and for quality control testing. Since the test is conducted under clean and dry laboratory conditions that are rarely encountered in practice, the prediction of materials from test results is next to impossible. Figure 18 illustrates a typical setup for an arc resistance test. The voltage is applied intermittantly and severity is increased in steps until the failure occurs. Arc resistance is measured in seconds to failure.

ASTM method D2132 outlines the procedure for determining dust and fog tracking and erosion resistance of electrical insulating materials. The test is carried out in a fog chamber with a standardized dust applied to the sample surface. Failure is characterized by the erosion of the specimen or tracking. ASTM D2302 also describes the test for differential wet tracking resistance of electrical insulating materials with controlled water-to-metal discharges. The inclined specimen is partially immersed in a water solution of ammonium chloride and a wetting agent. Failure is characterized by tracking. ASTM D2303 describes the test for liquid–contaminant inclined plane tracking and erosion of insulating materials. In this test, the specimen is inclined at 45°, and the electrolyte is discharged onto the surface at a controlled rate, increasing the voltage at the same time. The failure is marked by erosion and tracking.

**Electromagnetic Interference/Radio Frequency Interface Shielding**

The explosive growth of computers, telecommunication, and other electronic devices has created an urgent need for understanding and developing test and measurement techniques and standards for electromagnetic interference (EMI) and radio frequency interface (RFI) shielding. All electronic devices are required to have electromagnetic compatibility. It is a phenomenon caused by unrestricted

Arc resistance electrodes intermittently subject the specimen surface to a high-voltage arc until a conductive path is formed.

**Fig. 18** Arc resistance test. (Courtesy Bayer Corporation)

electrical and magnetic energy that escapes from any electrical device and reaches a second unintended device. It is called EMI if the receiving device malfunctions as a result of this pollution. Any electrical signal falling between direct current (DC) electricity and the gamma-ray frequency region of the electromagnetic spectrum can be sources of EMI. For most practical purposes, the majority of EMI problems are limited to a part of spectrum from 1 kHz to 10 GHz. This portion of electromagnetic spectrum is known as the radio frequency interface (RFI) band and covers the radio and audio frequencies. EMI of some form is experienced by us everyday. Some of the most common sources of EMI are lightning, static electricity, television and radio receivers, electric motors, electric appliances, paging system, and radar transmitters. Some of the most common receptors of EMI are microprocessors, computers, hi-fi equipment, electronic measuring equipment, radio and television receivers, remote control units, aircraft navigation systems, and humans and animals.

The fact that electronic devices are both sources and receptors of EMI creates a twofold problem. Since electromagnetic radiation penetrating the device may cause electronic failure, manufacturers need to not only protect the operational integrity of their product but also must comply with the regulations aimed at reducing electromagnetic radiation emitted into the atmosphere.

The switch from metal to plastics as a housing material for electronic equipment has contributed to the EMI shielding issue. Plastics are insulators to electrical energy, so EMI waves pass freely through unshielded plastic without any

impedance or resistance. Metals, being conductors, reflect or absorb electromagnetic energy, and unwanted electrical energy is easily grounded. Shielding, the term used to describe the effective “blocking” of EMI, is provided by a conductive barrier that harmlessly reflects or transmits electrical interference to ground.

EMI/RFI shielding of electronic devices is achieved in many different ways. Two of the most common ways to achieve shielding is either to coat the plastic housing with conductive material or to make the housing material itself conductive. The second method of using conductive plastics for shielding effectiveness is relatively new and for the most part in research and development stage with limited commercial applications. Coating methods on plastic parts are by far the most popular and the most varied shielding techniques. Basically, they all involve coating the finished plastic housing with a layer of conductive material to create a faraday cage (a concept that an enclosed conductive housing has a zero electrical field), resulting in a EMI shield. Electroless plating method is also gaining popularity as an alternate method to conductive coatings.

### **Shielding Effectiveness Measurement**

Electromagnetic energy is most effectively measured in terms of attenuation. Attenuation is the amount by which the intensity of an electromagnetic signal is reduced by the introduction of a shielding medium. The attenuation is measured in decibels (dB) and is the ratio of the field strength without the shield to the field strength with the shield. Shielding effectiveness measured in decibels is a logarithmic scale, which means that an attenuation measurement of 50 dB is ten times more effective than a measurement of 40 dB.

Four basic techniques for measuring shielding effectiveness have been developed:

- Open field testing
- Shielded box
- Coaxial transmission line
- Shielded room

### **Conductivity Measurement**

In production, conductivity testing becomes an important means for quality control of individual parts as well as for part-to-part testing of assembled enclosures. Surface resistivity, volume resistivity, and ohms-per-square measurement are common tests for both conductive coating and conductive plastics and used as a quick and practical quality check.

**Surface Resistivity.** Surface resistivity measures the resistance of a material to moving or distributing a charge over its surface. The lower the surface resistivity value, the easier a material will redistribute an electrical charge over its entire surface area. Surface resistivity test procedure is described in ASTM D257.

Surface resistivity meters that allow direct reading in ohms/square measurement are most commonly used. One of the meters uses a probe with an inner and an outer ring. A charge is applied to the inner ring, which travels over the

surface of the material and then is recorded by the outer ring. In addition to these resistivity meters, manufacturers often use a digital ohmmeter to measure the point-to-point resistance between two probes in contact with metallic coating. This method utilizes two spring-loaded probes that are placed at designated positions on the part or between two areas on mating parts. The conductivity between the two points is measured. This method is illustrated in Fig. 19.

**Volume Resistivity.** Volume resistivity measures the ability of a material to resist moving charge through its volume. The lower the volume resistivity of a material, the more conductive the material. This test procedure is also described in detail in ASTM D257.

**Ohms-per-Square Testing.** Ohms-per-square testing involves the placement of a probe on a surface of the part. This probe has two outside blocks of equal geometry and a space of equivalent dimension between the blocks. The probe is simply placed on the part and conductivity is measured. The test is extremely useful in quick checking the coated parts to verify minimum thickness of a conductive film. However, the test is not very effective for determining the overall conductivity of a coating across an actual part.

#### 4 WEATHERING PROPERTIES

The increased outdoor use of plastics has created a need for a better understanding of the effect of the environment on plastic materials. The environmental factors have significant detrimental effects on appearance and properties. The severity of the damage depends largely on factors such as the nature of the environment, geographic location, type of polymeric material, and duration of exposure. The effect can be anywhere from a mere loss of color or a slight crazing and cracking to a complete breakdown of the polymer structure. Any attempt to design plastic parts without a clear understanding of the degradation mechanisms induced by the environment would result in a premature failure of the product. The major environmental factors that seriously affect plastics are:

Fig. 19 Point-to-point resistance measurement. (Courtesy Enthone-EMI Corporation)

1. Solar radiations—ultraviolet (UV), infrared (IR), X-rays
2. Microorganisms, bacteria, fungus, mold
3. High humidity
4. Ozone, oxygen
5. Water: vapor, liquid, or solid
6. Thermal energy
7. Pollution: industrial chemicals

The combined effect of the factors mentioned above may be much more severe than the effect of any single factor, and the degradation processes are accelerated many times. Many test results do not include these synergistic effects, which almost always exist in real-life situations.

**UV Radiation.** All types of solar radiation have some sort of detrimental effect on plastics. Ultraviolet radiation is the most destructive of all radiations. The energy in ultraviolet radiation is sufficiently strong enough to break molecular bonds. This activity in the polymer brings about thermal oxidative degradation that results in embrittlement, discoloration, and an overall reduction in physical and electrical properties. Xenon arc lamps, fluorescent lighting, sun lamps, and other artificial sources also emit a similar type of harmful radiation. Other factors in the environment such as heat, humidity, and oxygen accelerate the UV degradation process.
